UMPs Spot urine typically requested, first morning sample is preferred but not required.	The test for MPS. In Hurler or Hunter syndrome and other dysmorphic conditions it can help to guide specific choice of enzyme or DNA testing. More controversial is the use of the test for screening patients with nonspecific developmental disability, including autism. However, Sanfilippo syndrome is an MPS that yields no coarse features for the first decade or more, and no skeletal problems; it presents as nonspecific developmental disability and classic autism and is fatal; genetic counseling is indicated for affected families. Ideally, for UMPS testing, send to a laboratory that will fractionate the mucopolysaccharides if the screen is positive, to avoid family stress by requesting follow up sample.
CDG Serum is the sample typically used for screening (red or tiger top).	Evaluation of the level of protein glycosylation is a screening test for CDGs. The extreme complexity and variety of glycosylation of proteins limits the sensitivity of screening, so false-negative results are possible, and false-positive results can occur especially in liver disease. The screening test is nevertheless powerful and can be diagnostic in some cases. The original and more limited test is immunoelectrophoresis of transferrin, with simple N-linked sugars; it is important to distinguish the test for CDG from the test of transferrin glycosylation to monitor alcoholic liver disease. The more powerful screen examines both transferrin and apolipoprotein E, which has O-linked glycosylation. Still more sensitive and specific is tandem mass spectroscopy to examine a broad range of proteins with more varied combinations of carbohydrates.

AA, amino acids; ACP, acylcarnitine profile; CDG, congenital disorders of glycosylation; CSF, cerebrospinal fluid; MPS, mucopolysaccharidosis; OA, organic acid; PAA, plasma amino acid; UAA, urine amino acid; UMPS, urine mucopolysaccharide; UOA, urine organic acid.

seizures of postinfectious etiology, inclusion of non-ketotic hyperglycinemia and glucose transporter in the differential diagnosis would lead to the additional collection of a sample for CSF amino acids. For those conditions, testing also must include the simultaneous collection of blood amino acids and blood glucose to calculate the ratios of glycine and of glucose in CSF and blood. These tests can be included in the evaluation by the astute neurologist with no advance planning, and in some cases, can even be “added on” to the analysis of samples collected for other purposes.

For some special testing, however, advance planning is critical. As an example, analysis of CSF for neurotransmitters requires both special collection starting with the first drop of fluid and immediate transport and freezing at a very low temperature. Advance planning is also needed for tissue biopsies if the sample is to be appropriately handled for biochemical testing. When a liver biopsy does not reveal an infectious cause of liver failure or a muscle biopsy does not reveal a congenital dystrophy as a cause of hypotonia and weakness, mitochondrial disorders then rise to the top of the differential diagnosis. Unless the sample was collected with that possibility in the differential

diagnosis, the sample will not have been collected and handled in a manner that permits appropriate testing.

DNA studies increasingly have the power to confirm specific diagnoses and often to replace invasive studies. Although testing of the whole exome is beginning to be useful, it is most efficient to focus DNA testing to address a specific condition or a panel of disorders. A combination of history, physical examination, and other appropriate studies such as imaging and biochemical testing should be used to select any DNA testing.

DNA testing varies in sensitivity. The sensitivity of the testing depends both on the condition and the methodology used in testing (eg, whether the laboratory tests only for commonly recognized mutations, whether a gene or a panel of genes is sequenced, and whether there is examination for deletions in the gene that would be missed by sequencing). For some conditions and with some methods of testing, the likelihood that DNA testing will identify a condition that is present can be well over 95%. For other conditions the sensitivity of the testing is substantially lower, and in some the specific gene is not identified or testing is not available for some reason. Abnormal results of DNA testing can confirm a diagnosis, especially for

X-linked and autosomal dominant conditions. For autosomal recessive conditions, the finding of 2 different disease-causing mutations is diagnostic if there is evidence that the 2 mutations are not on the same chromosome. Normal results of DNA testing seldom completely exclude a diagnosis but can be used to adjust the providers' ranking of conditions in the differential diagnosis.

Some laboratories and some jurisdictions require patient/parental consent for DNA testing. As with certain other studies (eg, blood typing in a newborn or tissue typing for transplant), it may be possible to find nonpaternity with DNA testing; however, if the patient and not the parents undergoes DNA testing, then nonpaternity could be identified only if a parent has previously been tested. The testing of mitochondrial DNA is a special case in which finding certain types of mutations in the patient provide information about risk for the patient's mother and all maternal relatives to be affected, even if they are symptom free. Specific counseling about that possibility should be done before testing is performed, whether or not the state or the laboratory requires consent with the sample. Sample handling for DNA testing is not particularly difficult, so collection may be simple, but there are special issues in payor approval of these often costly studies. Testing should not be undertaken without considering coverage so that the family and the physician are not exposed to unexpected costs. These issues should all be considered before collecting samples for DNA evaluation, and if the physician is not comfortable providing complete pretest counseling, the assistance of a genetics professional should be sought.

There are special considerations for the biochemical testing of the patient who presents with what may be an IEM and is not expected to survive. In addition to the risk that future offspring to the family may be affected, there is the risk that an already living sibling or other relative could be affected without having yet experienced symptoms. The appropriate use of laboratory testing to make the diagnosis can provide answers to a family and in some instances prevent inappropriate prosecution of family members suspected of abuse or neglect. In addition, using laboratory testing to suspect or confirm a diagnosis of IEM can be life-saving to other family members. Many of the studies listed in Table 291-2 can be performed in the dying child. If the suspicion of an IEM is sufficiently high, the physician should attempt to offer a "metabolic autopsy." This can only be performed if the necessary resources are available through pathology, including immediate (ideally within 1 hour of death) collection and preservation of tissue samples at  $-70^{\circ}$  to  $-80^{\circ}\text{C}$ . These samples could then be used for any enzyme assays that would be indicated by the results of testing of analytes on samples collected either before or at the time of death. The testing of stored samples that might be ordered after the death of the child is not expected to be covered by insurers, and therefore any discussion of the option of "metabolic autopsy" must include the consideration of possible costs. As with most testing in medicine, testing does not guarantee a diagnosis. A lower cost but limited screening option is to send a sample on filter paper to

one of a few laboratories that analyze amino acids and an ACP on autopsy sample. Some laboratories also will accept and bank a sample of DNA for a modest fee, in case the family might require future DNA testing.

### Imaging

Although there is no single imaging test that is specific to the diagnosis of an IEM, imaging is a critical part of the diagnostic evaluation and monitoring in the management of many categories of IEMs. In some cases, the result of imaging is the critical element suggesting a specific diagnosis. An important example is an echocardiogram to identify a cardiomyopathy that should suggest the possibility of disorders of fatty acid oxidation or carnitine, glycogen storage, or disorders of mitochondrial energy metabolism. An echocardiogram is used also in the monitoring of individuals with some of these conditions and of patients with certain organic acidemias and lysosomal storage disorders. Skeletal films and survey in a child with slowing growth who shows dysostosis multiplex of certain lysosomal storage disorders or with the stippling of the epiphyses of certain peroxisomal disorders can narrow the diagnosis to a specific category of IEM. Magnetic resonance imaging (MRI) can show changes in basal ganglial white matter of Leigh disease, suggesting that the child will almost certainly have one of the many disorders of mitochondrial energy metabolism. An MRI can show white matter changes in the occipital region that suggest the peroxisomal disorder adrenal leukodystrophy.

When ordering any imaging, the physician should consider whether special views or studies might be of use. For example, for a skeletal survey, views of the lateral spine are key to identifying dysostosis multiplex. When the imaging testing requires special preparation, for example, sedation for an MRI, it is wise to consider whether additional studies that also require sedation can be done at the same time and, in the case of magnetic resonance spectroscopy (for lactate, creatine, or other metabolites), in the same scanning session.

### Other Diagnostic Procedures

To obtain appropriate samples for examining amino acids, neurotransmitters, and some other analytes, it is sometimes necessary to perform a lumbar puncture to collect CSF. Biopsies may also be key to the diagnosis, including a relatively simple biopsy of the skin (for histology or for culture of fibroblasts for biochemical testing) or of conjunctiva for histology. When histology is useful in the examination of tissue, special stains and electron microscopy are likely to be helpful. Therefore, the pathologist should be specifically included in the discussion of the differential diagnosis to ensure that appropriate sample handling permits the use of the proper strategies in the laboratory. Biopsies of muscle and liver can be especially useful when properly analyzed for histology, histochemistry, and electron microscopy and when properly handled so that enzyme assays and other biochemical testing can be done.

Various functional studies can help in the diagnosis and possibly the monitoring of IEMs. Some examples

include electroencephalography (EEG), which shows nonspecific features that the neurologist reads as suggesting an IEM, or specific findings of hypsarrhythmia suggesting nonketotic hyperglycinemia or, in some older individuals, the triphasic waves that suggest hyperammonemia. Nerve conduction or the electromyogram are abnormal in some IEMs. Some IEMs will affect gastric or intestinal motility.

In some instances, specific physiologic challenges are useful or necessary to establish a clinical diagnosis and to determine appropriate management. These can include challenge by diet, by exercise, by fasting, or with specific medications (eg, allopurinol to test for the most common urea cycle disorder, or glucagon in testing for glycogen storage disease). Challenges can be dangerous, and details of how to perform such testing is well beyond the scope of this chapter. Some challenges can be performed on an outpatient basis, and some should be done only in an intensive care unit with secure vascular access. Challenges to diagnose an IEM should be undertaken in consultation with a specialist in the particular condition. In many cases there may be overlap between the evaluation for endocrine and IEM conditions that can cause a specific presentation, especially when the presentation includes hypoglycemia. The joint development of protocols for evaluation between endocrinology and biochemical specialists is advisable. In particular, if medium-chain acyl-CoA dehydrogenase deficiency (MCADD) is on the differential diagnosis, a child should not undergo fasting until an ACP has shown no evidence of that condition. In addition, providers should be aware that the action of glucagon is to increase lipolysis, and any child with a disorder of fatty acid oxidation will experience worsening symptoms if glucagon is given as part of a challenge.

## CLASSIFICATION

IEMs are classified according to the metabolic pathways (Table 291-1). Some experts classify IEMs according to whether they cause acute toxicity or chronic disease; for the PCP and the nonmetabolic specialist, it may be most appropriate to consider the IEMs, as they are most likely to present. The following clinical scenarios are offered for practical consideration.

### Clinical Scenarios

#### **The Acutely Ill Patient (Shock, Possible Septicemia, Altered Mental Status)**

Inborn errors of the amino acids, organic acids, the urea cycle, fatty acid oxidation, mitochondrial metabolism, and several others may cause severe symptoms with a gradual or sudden onset. When altered mental status is apparent or acid-base status is out of proportion to the physical findings, or when there is a history of prior episodes in which the child has been diagnosed as having dehydration with intercurrent illnesses, suspect an IEM. An IEM should certainly be considered when poisoning is suspected, unless a specific ingestion is known or suspected based on history or characteristic symptoms. Poisons can be created by intrinsic metabolic processes. Finding an infection or nonaccidental trauma does not exclude

an IEM. Be sure to examine ammonia levels and liver functions to avoid missing important clues to a diagnosis. Checking plasma ammonia is especially important in any neonate suspected of sepsis with either gastrointestinal symptoms or altered consciousness, especially because expanded newborn screening does not yet detect all urea cycle defects. Moreover, neonates may become symptomatic even before the results of a newborn screening are available.

When evaluation begins, remove all protein and lipids from the nutritional management and all sugars except glucose. Provide adequate glucose to stop catabolism, which requires a glucose infusion rate (GIR) of 10 mg/kg per minute in the neonate and 6 mg/kg per minute in the older child. The purpose of this GIR is to prevent catabolism and is not driven by blood glucose level. If a patient with an IEM has elevated blood glucose, insulin should be used to move glucose into cells. Because a very small fraction of IEMs worsen with these GIRs, all patients suspected of being in metabolic crisis should receive intravenous glucose initially unless a diagnosis known to require a low (<4 mg/kg per minute) GIR is known. Patients known to require unusually low GIR should carry an emergency letter with instructions. Measure ammonia and consider measuring lactate and pyruvate. Specific diagnostic testing for an IEM in this setting begins with plasma amino acids (PAA), UOA, ACP, and any other studies as indicated by presentation (Table 291-1 and Table 291-2).

#### **Child With Dysmorphic Features and Malformations**

The classic dysmorphic syndromes resulting from IEMs are Smith-Lemli-Opitz syndrome caused by a failure of cholesterol synthesis (classic presentation—small size, feeding disorders, characteristic facial features with cleft soft palate, heart defect, pyloric stenosis, syndactyly of the second and third toes, extra-axial polydactyly, hypospadias) and Zellweger syndrome caused by a failure of biogenesis of peroxisomes (cerebrohepato renal syndrome with characteristic facial features including high forehead and flat face, liver and renal cysts, and extremely low tone). Other conditions involve brain malformations, especially the disorders of mitochondrial energy metabolism and the congenital disorders of glycosylation. Further, many of the mucopolysaccharidoses have characteristic coarse features of face and progressive skeletal dystrophy.

Patients with some chromosomal abnormalities are at increased risk for an IEM. For example, patients with contiguous gene deletions may have only 1 carrier parent for an IEM if the gene is in the deleted region. Patients with uniparental isodisomy are homozygous for all genes on the affected chromosome and are therefore affected with an IEM if the parent providing that chromosome was a carrier. The diagnostic evaluation is guided by the history and physical examination.

#### **Child With Failure to Thrive, With or Without Vomiting**

Most patients with FTT do not have an IEM, but many patients with an IEM present with FTT. The PCP

should consider an IEM particularly if vomiting persists despite reflux management and certainly if there is any alteration in development, neurologic findings, or neurodevelopment. Brain growth and neurodevelopment in children with nutritional FTT are usually preserved unless the malnutrition is severe. Be certain to examine acid-base status and remember that vomiting causes alkalosis, never acidosis, unless the patient is vomiting bile or has developed poor perfusion. Check liver functions and CBC, and examine the MCV to avoid missing clues that further studies should be undertaken for an IEM. Begin an evaluation for an IEM with blood amino acids (PAA or SAA), UOA, ACP, and total and free carnitine.

***Child With Abnormal Neurologic System (Early Hypertonia, Late Hypotonia, Episodic or Progressive Ataxia or Other Movement Disorder, Atypical or Unresponsive Seizures, or Episodic Altered Consciousness)***

Almost any category of IEM can cause abnormal neurologic presentations. Careful attention to the history can yield clues and lead to early diagnosis and treatment. Examine acid-base status and liver function. Assess for macrocytosis and collect blood amino acids (PAA or SAA), UOA, and ACP. Measure blood ammonia in patients with acutely altered mental status or acute ataxia. An ophthalmologic examination for evidence of cataracts or retinopathy may provide clues to a specific IEM. When collecting CSF, examine lactate and amino acids and consider planning in advance for the special handling of samples for measuring neurotransmitters and other metabolites of IEMs. For the evaluation of an IEM as the cause of seizures, collect blood glucose and PAA immediately before a lumbar puncture so that the ratio of CSF to plasma glucose and glycine can be evaluated. When planning an MRI, ask also for magnetic resonance spectroscopy to examine lactate for clues to inborn errors of energy metabolism.

***Child With Intellectual Disability and Autism (Especially With Slowing Development, Developmental Plateau, and Regression)***

Regression should always signal the need for an immediate evaluation for an IEM to identify those who will benefit from therapy and because many conditions that cause regression are IEMs, including some that are both fatal and autosomal recessive. For example, a boy with regression of development may need evaluation for X-linked adrenoleukodystrophy. However, at the initial presentation of a child with mental developmental disability or autism, it is not always clear whether the patient will be stable or improve, or will develop increased problems. History and examination can help to distinguish those in need of more aggressive evaluation, such as those with hypotonia. There are no physical findings that exclude the presence of acidosis, liver disease, or macrocytosis. Therefore, basic studies of electrolytes, liver health, and CBC are appropriate for all children presenting with intellectual disability unless a clear cause of all presentations is known.

The recommendations for the use of more specific studies for an IEM in the absence of regression or other clues on history or examination (such as hypotonia) are variable. The addition of routine testing for IEMs in children with developmental disabilities and an otherwise normal history and examination has undergone few studies and is generally agreed to have low yield. However, testing of blood amino acids and urine mucopolysaccharide is not costly, and the positive effect of making a diagnosis can be extremely high; therefore, many experts typically urge that all patients with an intellectual disability or autism should undergo an evaluation of blood amino acids (for phenylketonuria [PKU] and homocystinuria, which could have been missed on newborn screening; some cases of PKU in particular are indistinguishable from autism) and urine mucopolysaccharides (for Sanfilippo syndrome, which presents without abnormal physical features at onset and may be indistinguishable from classic autism). The most recent recommendations of the American College of Medical Genetics address the issue of metabolic testing in the child with autism spectrum disorder in some detail.

***Child With Single or Multiple Organ Failure***

Renal failure from Fabry disease, liver failure from tyrosinemia, and cardiomyopathy from fatty acid oxidation or Pompe disease are potentially reversible. Other conditions are less responsive to therapy, such as liver or bone marrow failure in children with mitochondrial disease, but awareness of the diagnosis can help with management. For example, it is necessary when possible to avoid valproic acid when treating children with seizures from an IEM. Be aware that an infection may be the trigger leading to the presentation of an IEM and that some IEMs include immune deficiency that can increase the risk for infections. The evaluation for an IEM in a child with single or multiple organ failure typically includes testing for those IEMs known to cause the specific presentation (eg, organic acidopathy as cause of pancreatitis, or tyrosinemia as cause of liver failure) but in general includes the evaluation of blood amino acids, UOAs, ACP, and carnitine (total and free), in addition to any other disease-specific testing.

***Child With Stroke or Clotting Disturbance***

One of the standard presentations of classic homocystinuria resulting from cystathionine  $\alpha$ -synthase deficiency is thrombotic stroke. Up to half the patients with classic homocystinuria and most with variant types are expected to be missed by newborn screening. Although some patients may have marfanoid habitus or a history of developmental disability, many others have no signs or symptoms of an IEM as the cause of stroke. Total homocysteine, blood amino acids, and UOA should be included with studies for other genetic causes of stroke. Also, when evaluating these children consider the possibility that the child has experienced a strokelike episode of MELAS syndrome (mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes) at initial presentation and include Fabry disease and congenital disorders of glycosylation in the differential diagnosis.

## SPECIAL CONSIDERATIONS IN THE BIOCHEMICAL EVALUATION OF INBORN ERRORS OF METABOLISM

Table 291-2 summarizes the routine or common biochemical tests for the primary care or nongenetics pediatric specialist in the evaluation of a child with a suspected IEM. Begin with more general metabolic tests and use additional specific tests as indicated by presentation and results of initial testing. Plans for special studies such as enzyme assays and DNA testing can be developed with the genetics team, but initial testing should typically be initiated before a consultation. A key to suspecting IEMs is understanding the meaning of key results in routine testing. For example, hypoglycemia in a previously healthy toddler or older child with normal growth could be because of acute-onset endocrine disease (eg, from an insulin-secreting tumor). However, these are rare in children, and hypoglycemia from poisoning or an IEM (especially disorders of fatty acid metabolism) is more common than insulin-secreting tumors in a previously healthy toddler. An important IEM that causes hypoglycemia in childhood is MCADD, which affects approximately 1 in 10,000 white children. However, it is equally important for the pediatrician to know that normal glucose levels do not exclude IEM and that patients with MCADD have died with normal glucose levels.

Screening the healthy neonate for an IEM is discussed in Chapter 29, Screening for Genetic-Metabolic Diseases. For the symptomatic patient, an investigation for IEMs begins with a careful examination of routine metabolic studies followed by specific studies. For the patient with a developmental disability who is not acutely ill, examine CBC, electrolytes, and liver function test results because abnormalities in any of these would suggest that further studies are indicated. There is not necessarily any physical finding in patients with macrocytic anemia, renal tubular or metabolic acidosis, or liver dysfunction. For the acutely ill patient, inappropriately low ketosis is also an important clue and can be detected with urinalysis. Acidosis out of proportion to clinical status or the presence of alkalosis should increase the suspicion for an IEM. Be certain to consider an IEM as the cause of findings on imaging. For example, patients with mitochondrial disease may have strokelike episodes, true stroke, or evidence of brain injury in a pattern indistinguishable from hypoxia. They may also have classic presentations that are clearly because of IEM, such as the white matter disease of adrenoleukodystrophy or the basal ganglia injury and extra-axial fluid of classic glutaric acidemia.

Check ammonia level in any patient with acutely altered mental status or acute ataxia and consider ammonia level testing in a neonate with suspected sepsis; Table 291-2 shows cautions to be exercised during collection and handling. In the acutely ill patient or patient with hypotonia consider also testing lactate levels. Be aware that lactate is also sensitive to collection and handling but that unlike ammonia, lactate levels can change in minutes. Lactate can be

normal on a sample collected incorrectly, so it will not be possible to be sure incorrect handling is the cause of elevation. Collecting lactate incorrectly may therefore lead to added testing that could have been avoided if the sample were collected properly (Table 291-2).

Testing for biochemical analytes is guided by clinical presentation. Like testing for toxins, the yield for specific biochemical (analyte) testing varies with the presentation. Biochemical studies of the patient with ammonia level 100 times the upper limit of normal is highly likely to identify a disorder of the urea cycle. Plasma amino acids in a patient with nonspecific developmental disability will have low yield compared with studies such as comparative genome hybridization. However, the total cost of testing the most commonly measured analytes (blood amino acids, UOA, ACP, carnitine total and free, CSF amino acids, and urine mucopolysaccharides) is a very small fraction of the cost of the care of the acutely ill patient or the neurodevelopmentally disabled child; typically that panel of studies can be done for less than the cost of an MRI or comparative genomic hybridization. In addition, patients identified with chromosomal deletions are at higher risk than the general population for IEM. For example, boys with certain deletions of the X chromosome have glycerol kinase deficiency causing recurrent episodes of acidosis and altered mental status, and also have Duchenne muscular dystrophy.

Testing of DNA can assist in the diagnosis of an IEM. As with any DNA testing, be sure that the interpretation (including sensitivity) is discussed with genetic experts if experience in interpreting these test results is lacking. Consider, too, whether the purpose of DNA testing is to guide management of the patient or is to determine whether it will be possible to provide carrier testing to other family members or prenatal testing in the future.

Because most IEMs are autosomal recessive, testing of parents (DNA or enzyme assay) can provide critical help in making or excluding a diagnosis. For example, if galactosemia is suspected in a newborn who has received a transfusion, testing of the mother that demonstrates she is not a carrier will virtually exclude the possibility that galactosemia is the cause of the presentation (paternal uniparental isodisomy from a carrier father could still cause galactosemia, but this is rare). However, DNA testing of family members is not always necessary and can lead to problems. For example, when a child's father has just been diagnosed with hemochromatosis with homozygosity for the common mutation, testing the child and finding the mutation does not add any new information to guide management. Finding no mutation suggests nonpaternity.

A special consideration in testing for IEMs is in the acute setting when the child is dying. When a diagnosis that excludes an IEM is not conclusively established, studies for IEMs could identify living or future relatives at risk and in need of treatment. In addition, studies for IEMs could establish the cause of death and prevent inappropriate prosecution of a parent. Samples for IEM testing should therefore be sent

even if there is no expectation that the patient will respond to efforts at resuscitation. Some samples can be collected after death; however, a full metabolic autopsy requires immediate collection of samples suitable for testing of analytes and enzymes within the first hour after death and requires collaboration of emergency or intensive care unit care providers, pathology and metabolic geneticists, and in some circumstances, permission from a medical examiner.

## MANAGING INBORN ERRORS OF METABOLISM IN PEDIATRIC PRIMARY CARE, ON THE WARDS, IN THE EMERGENCY DEPARTMENT, AND IN THE INTENSIVE CARE UNIT

### Treatment Approach

Many IEMs have specific treatments that can reduce or even prevent disability or death. The first step in managing an IEM in the primary and specialty pediatric practice is making the diagnosis so that appropriate treatment can be offered. The diagnosis can only be made when IEMs are suspected and appropriate testing initiated. The stakes can be high for emergency recognition of IEM, for example, in a child with overwhelming acidosis or a child in a coma that proves to be caused by hyperammonemia. The primary care physician or nongenetics pediatric specialist typically works with a geneticist in management of IEM; however, management is often initiated in the acutely ill patient by excluding potentially harmful dietary components and by providing glucose in amounts sufficient to prevent catabolism. It should be emphasized that patients who have an IEM, when stabilized and in the chronic phase of management, typically are not hospitalized because of the underlying IEM. Rather, a viral illness, fasting, or another disorder will tip the balance and cause a metabolic crisis unless the child is treated promptly. Therefore, pediatricians are on the front lines of management for these children. In addition, the importance of maintaining vaccination schedules as recommended by American Academy of Pediatrics and obtaining annual influenza (killed) vaccinations in both the affected child and family members are simple yet critically important aspects of pediatric care.

### Specific Treatment

Specific management is available for many IEMs, such as the branched chain amino acid–restricted diet for maple syrup urine disease or the provision of cofactor for B<sub>6</sub>-responsive seizures. Some conditions that in the recent past were untreatable and fatal (eg, Pompe disease) can now be treated with enzyme infusions that can reverse some symptoms and prevent further injury. Specific therapy for long-recognized conditions continues to evolve. For example, some individuals with PKU are now recognized to respond to therapy with the cofactor biotin. PKU is also an example of an IEM that requires lifelong therapy. Patients with poor compliance in late childhood and teen years are at risk for developing progressive white matter disease of the brain, and because elevated phenylalanine is a

teratogen, young women with poorly controlled PKU will have offspring with intellectual disabilities and malformations. Other examples of the adverse consequences of poor compliance are liver cancer in those with glycogen storage disease or a stroke in those with homocystinuria.

For other IEMs, the specific current treatment consists solely or primarily of supportive, symptomatic management. Patients and families often wish to participate in experimental therapies, especially for conditions that are fatal and have no proven effective therapy. Anticipatory guidance is critical for managing all IEMs, and genetic counseling is important for families and for the patients themselves when they consider future reproductive risks.

Collaboration is the basis of the specific management for all IEMs, especially for those conditions for which there are risks for metabolic crises requiring emergency management. The metabolic expert should provide—and the family, primary care physician, and other specialists should follow—any relevant instructions both for chronic care and in treating any emergency. In some cases there will be specific adjustment of care if a child is acutely ill, and in all cases—even if the family has made a decision involving limitation of or end-of-life care—it will be appropriate to provide supportive care. Typically in an acute emergency, after the ABCs, the most important part of care for the child with an IEM is the prevention of catabolism. It is critical that the emergency provider distinguishes between concern for catabolism and concern for blood levels of glucose. Except for certain glycogen storage disorders, the pathophysiology of most IEMs that can present with acute crisis is such that blood glucose remains normal until metabolic balance decompensates past a critical point. For example, some children with MCADD have died with normal blood sugar levels. When a patient's metabolic specialist instructs the emergency clinician to administer intravenous glucose at a specific rate, that should be done when the patient is unable to tolerate enteral intake, regardless of the blood glucose level; that child should continue to receive intravenous glucose until enteral intake is appropriately tolerated. The keys to management are understanding the pathophysiology of the condition and the principles of management for each patient and having and using a plan for both chronic and acute care.

### Ongoing Care

#### Follow-up

Management is a collaborative effort with the metabolic specialist or geneticist and any other appropriate medical specialists. For example, management of cystinosis typically requires collaboration with nephrology and ophthalmology specialists, and the management of Pompe disease involves a cardiologist. For many IEMs there is a role for the specifically trained metabolic dietitian or the genetics or metabolic nurse and genetics counselor, working as a team with the geneticist to provide care and support for the pediatric physician and other pediatric specialists. The transition to adult care is an issue for all pediatric patients with chronic disease. In many cases the genetics team will remain constant after the transition to adult care

because the metabolic genetics team typically cares for adults and children.

### **Complications and Prognosis**

The prognosis and complications of IEMs vary with the specific condition. For some IEMs, response to therapy is so predictably excellent that the only “complication” is the need for the affected child to remember that failure to continue therapy is life-threatening, as in the case of biotinidase deficiency. For other conditions, available therapy is limited and complications and eventual death are not preventable.

In some cases in which response to therapy directed at the IEM is expected to be excellent, the child may have already sustained severe neurologic or other injury as a result of the IEM before diagnosis. This is particularly true with some disorders of fatty acid oxidation and some organic acidurias. In these cases the prognosis for the IEM may be excellent, whereas the prognosis for the child may include long-term chronic health and developmental problems. Preventable morbidity from treatable conditions is the justification for newborn screening when it is feasible. The prevention of morbidity and mortality from an IEM is also the reason for considering an IEM even in the dying child or the child with irreversible injury for an opportunity for a better outcome in future offspring or affected siblings.

Complications of many IEMs involve neurologic dysfunction (central and peripheral), cardiomyopathies, liver disease or liver failure, growth failure, intestinal dysfunction, deafness, eye disease including cataracts and retinopathy, muscle disease including rhabdomyolysis, and single or multiple endocrine gland failures; some IEMs cause birth defects. Managing the complications of IEMs can involve multiple medical specialists. The complications of an IEM are also likely to require the attention of various specialists such as speech, occupational, and physical therapists and experts in special devices and education.

An important complication of the IEM is the effect on the family. Even when there is a simple and effective therapy, families are stressed by knowing that a child has a condition that threatens life or health and development. For many conditions a life-saving therapy involves substantial modification of ordinary living, such as with the use of restricted diet that affects family behavior and dynamics. Diagnostic evaluation and therapies can be costly and often inadequately covered by insurance, if covered at all; and there may be need for time-consuming efforts to secure such coverage. As with any child with a chronic disease, there can be substantial time involved in the daily care of a child and effects on other children. There is also the effect on families’ decisions about whether to have other children in the future, and there may be complicated interactions with the broader family both for support for the affected child and for disclosures of genetic risks.

### **Prevention**

There are 3 fundamental kinds of prevention.

First, for the affected individual, the goal is the prevention of the medical and developmental complications

of the IEM, by means of appropriate management. For conditions that can present with metabolic crisis, appropriate management includes especially avoidance of catabolism. In some cases prevention includes avoidance of certain known risks or triggers, including drugs that have adverse effects on relevant pathways, (eg, mitochondrial metabolism, the porphyria pathways, or the synthesis of cholesterol). The use of standard health care and prevention is critical, including use of all relevant vaccines; in almost every case the risk for metabolic crisis from a vaccine is less than the risk if the patient were to contract the condition against which the vaccine protects. For those with conditions that include metabolic crisis as part of the presentation, it is generally recommended to use killed vaccine for the patient and the family members. Although only a few IEMs are associated with immune deficiency, the risks of a live virus-inoculated family member to pass the infection to the affected individual must be considered. Attention to the transition process may help prevent lapses in monitoring and management as the child moves from pediatric to adult care.

Second, the IEMs are by definition genetic, and the recurrence risk within families is therefore significant. In some cases, a living individual is at risk and needs to be offered evaluation and care. In all cases, the family must be offered accurate information about the risk for recurrence. This information should be offered in the context of genetic counseling that assures respect for each individual’s and family’s unique beliefs and values. When there is the possibility of carrier or prenatal testing or other prenatal options, relevant factual information should be offered, along with the opportunity to explore whether and how they will choose to use such opportunities.

Finally, it is incumbent on the physician to offer whatever is possible to mitigate any adverse effects of the IEM and its consequences on the individual’s and family’s function. This includes efforts to secure necessary supportive or habilitative services. The affected individual and family should be offered the option to connect with other affected individuals, families, or support organizations.

### **WHEN TO REFER**

The primary care physician and the emergency medical care provider should refer, or at least discuss the possibility of referral, to an appropriate specialist when there are symptoms and signs that suggest inborn errors of metabolism (IEM) and especially when the newborn, infant, child, or adolescent presents with any of the following:

- Neurodevelopmental abnormalities, especially acute altered mental status and, most especially, recurrent or intermittent symptoms or progression, hypotonia after 1 year of age, or a movement disorder
- Acidosis out of proportion to systemic illness
- Hypoketosis for the state of nutrition and especially hypoglycemia
- Cardiomyopathy, liver failure, failure to thrive, and renal tubular acidosis, which are individually important presentations of IEM and, in

combination with each other or with abnormal neurologic status

- Positive result on newborn screening for an IEM
- Family history of IEM
- IEM suspected for any other reason
- No other cause for the presenting problem that is unequivocally and certainly the primary underlying cause of the presentation

In some cases, especially if the child is critically ill and certainly if there is regression, the referral should be directly to a geneticist who is an expert in IEMs. Children with cardiomyopathy, for example, should be evaluated carefully for a treatable IEM or multisystem IEM that could cause other organ failure, especially before transplantation. When a child is stable, it may be appropriate for the primary care physician to work with another specialist, such as a gastrointestinal or neurology specialist, to consider whether a genetics or metabolic referral is warranted.

### WHEN TO ADMIT

The child with IEM should be admitted if home management is not sufficient to keep the child out of crisis, for example, when the child cannot maintain anabolism. In some cases, a child needs to be admitted for invasive evaluation. Admission is likely to be a joint decision of the PCP, appropriate specialists, and the family.

### Chapter 292

## MÜNCHAUSEN SYNDROME BY PROXY: MEDICAL CHILD ABUSE

Meggan Goodpasture, MD; Sara H. Sinal, MD

Medical child abuse (MCA), more widely known as Münchausen Syndrome by Proxy (MBP), is a rare form of abuse involving the persistent fabrication of physical or mental illness in a child by an adult. MCA now goes by various names, including pediatric condition falsification, factitious disorder by proxy, or fabricated or induced illness. It was first described in 1977 by Meadow, an English pediatrician. The name is derived from Münchausen syndrome, the condition of self-inflicted illness in adults. Compared to other forms of child abuse, MCA has proved to be a form of child maltreatment that is fraught with rather different diagnostic and legal problems. The perpetrator of

MCA, usually the child's mother, often evades the early detection of her noxious ministrations because the symptoms and signs she reports seem plausible and because she seems attentive and concerned. The perpetrator's history often sounds credible to the physician, suggesting a serious illness. Although physicians are educated to critically evaluate the reliability of a historian, pediatricians do not expect that a history is an elaborate lie. Once the diagnosis has been considered, definitive inclusion or exclusion may be problematic. As a consequence, protection of a child and any siblings may also prove difficult. Evaluation of the family, which can help shape therapy and which is useful only when the perpetrator is forthcoming, is often stymied by the mother's refusal to participate or her indignant denial of her role in causing the child's illness. Awareness of MCA also varies significantly among mental health professionals, and the perpetrator may deceive even an experienced therapist.

## DEFINITIONS

MCA occurs when a child undergoes or receives unwarranted medical care. Illness in a child is persistently and secretly simulated, produced, or both by a parent or someone who is *in loco parentis*. This circumstance often results in the parent's repeatedly bringing the child for medical care, and as a result the child undergoes multiple unnecessary medical procedures, both diagnostic and therapeutic. The definition specifically excludes physical abuse only, sexual abuse only, and failure to thrive that is solely the result of nutritional or emotional deprivation. In the context of this syndrome, the term *simulated* means that the caregiver or perpetrator fabricates the child's symptoms. For example, the caregiver may repeatedly report that the child has episodes of stiffening, shaking, or decreased level of consciousness, when, in fact, these episodes never occurred. The term *produced* means that the caregiver or perpetrator secretly interferes with the child's body to produce symptoms or signs in the child. Examples include surreptitious suffocation to cause apnea, or administering unprescribed medicines or substances such as a laxative to produce diarrhea.

The question regarding which diagnostic term should be used is important and has been the topic of much debate. Many questions surround the use of the term MBP. Should a pediatrician or a psychiatrist make the diagnosis of MBP? To whom should the term be applied, the parent or the child? The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV)*, described the syndrome as a "factitious disorder" that includes 2 components—the child as the victim and the caregiver adult as the perpetrator. The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5)*, uses different diagnostic terminology, including factitious disorder imposed on self and factitious disorder imposed on another. Furthermore, the American Professional Society on the Abuse of Children (APSAC) proposes that physicians use the term *pediatric condition falsification (PCF)* when focusing on the effect on the child, and *factitious disorder by proxy (FDBP)* when focusing on the perpetrator. It is clear from this discussion of

nomenclature that the multiple terms and definitions can be confusing for the physician. The American Academy of Pediatrics (AAP) has published a textbook by Roesler and Jenny that suggests the more inclusive term *medical child abuse (MCA)*. This term clearly indicates that abuse has occurred and allows the physician to focus on the harm sustained by the child as a result of unnecessary medical care. Additionally, it relieves the physician, who is responsible for caring for the child, from the responsibility of describing the psychiatric state or the motivation of the perpetrator.

## DEMOGRAPHICS

Hundreds of cases of MCA have been reported worldwide, although most cases of MCA likely go undiagnosed or unreported in the literature. Most of the literature concerning this form of maltreatment originates in the United Kingdom and the United States. Cases of MCA have also been reported from Canada; Australia; New Zealand; Western, Central, and Eastern Europe; Scandinavia; the Middle East; South America; the Indian subcontinent; Central America; Africa; Sri Lanka; Japan; and Singapore. Clearly, MCA is not a culture-specific disorder, nor is it confined to either a socialized or privatized medical system. In addition, apparently, the perpetration of MCA is not as uncommon as originally thought, although actual incidence is unknown. One study in the United Kingdom estimated the combined annual incidence of MCA by nonaccidental poisoning and nonaccidental suffocation as at least 2.8 per 100,000 in children younger than 1 year. Extrapolation of this data to the United States suggests somewhere between 200 new cases of serious MCA per year to at least 600 new cases per year of suffocation or intentional poisoning. A New Zealand study reported an incidence rate of 2 per 100,000 in children younger than 16 years.

In most cases of MCA, the perpetrator is the biological mother, although fathers, adoptive mothers, other relatives, babysitters, and nurses are occasionally implicated.

Boys and girls are victims almost equally, and no special trend is noted as to birth order. Curiously, however, although several children in a family may be abused sequentially, for more than 1 child to be targeted during the same time period is unusual, except during relatively brief transition periods. Typically, if the original child survives, then the child's medical troubles melt away when another child comes along and develops unusual and inexplicable illness.

Most victims of MCA are infants and toddlers. Presumably, the younger children are more commonly affected than older children because they are preverbal or semiverbal and relatively helpless physically. Although abuse of the children commonly begins in infancy or toddlerhood, a delay in making the correct diagnosis usually occurs. In 2 series, the average time from onset of symptoms and signs to diagnosis was 15 to 22 months, but the time span might be as long as 20 years or never. A rare report describes cessation of MCA not because of medical diagnosis, but rather because the school-aged victim threatened to disclose the caregiver's longstanding, painful, and disfiguring abuse. Older child victims of MCA, whose abuse may

have begun years earlier, may adopt the false symptoms and signs as their own. These children are less likely than young children to have illness produced and are more likely to have falsified reports of symptoms and medical history. Some evidence suggests that these children may go on to develop Münchausen syndrome themselves or some type of personality disorder. A few cases of adult victims of adult perpetrators of MCA have been reported.

In 1 series, 25% of MCA cases involved simulation only, 25% involved production only, and 50% involved both simulation and production of illness. Another, larger series showed that 57% of illness was produced. In 50% to 95% of cases, depending on the meta-analytic series, the perpetrator continued abusing the child in the hospital, often in the most egregious ways, and even in closely monitored settings, such as the pediatric intensive care unit. Short-term morbidity for the children, by definition, is 100%, much of it related to the diagnostic and therapeutic procedures, ordered by the physician. Long-term morbidity, defined as pain, illness, or both that causes permanent disfigurement or impairment, is harder to assess statistically than short-term morbidity. Approximately 8% of survivors of MCA have some kind of long-term morbidity as a result of complications of the attack or, rarely, complications or residua from medical procedures, including surgeries. This figure is probably an underestimate, however, and does not include long-term psychologic morbidity, which may be considerable.

Although assessing the mortality rate from MCA is currently impossible for methodological reasons, an important point to state is that some children die because of an ultimate fatal attack. Series death rates vary from 6% to 33%. In the largest series to date, apnea was the most common repeated symptom that preceded death. Almost all cases were infants and toddlers, and the causes of death notably featured suffocation and poisoning. Other causes of death have been described. Children as old as 8 years have been killed in the context of MCA. Furthermore, siblings of these children tend to die in alarming numbers, often with the misdiagnosis of sudden infant death syndrome (SIDS), and every reason exists to think that they died in a homicidal manner. Child fatality review teams are now common throughout the country and, with the expertise of multidisciplinary teams, are occasionally discovering cases of MCA that had been previously but incorrectly designated as accidental, natural, or undetermined manners of death.

### CLINICAL AND LABORATORY FINDINGS

Although signs, symptoms and laboratory findings in MCA cover an enormous spectrum, the most common serious presentation seems to be apnea. Seizures, feeding problems, bleeding, central nervous system depression, diarrhea, vomiting, fever (with or without sepsis or other localized infection), rash, allergy, and behavioral problems are also reported quite commonly. At no time, however, should any list be considered inclusive, because the understanding of the breadth of presentations of this syndrome is continually expanding. Table 292-1 lists some of the presentations of MCA.

Some child survivors of MCA are developmentally delayed as a result of the damage done by the inflicted illness or as a result of chronic hospitalization, enforced invalidism, or lack of stimulation. Malnutrition may be the result of the chronically inflicted illness, surreptitious withholding of food, or from prolonged emetic or laxative administration. MCA may also present as a *bona fide* chronic disease, when the caregiver has intentionally and surreptitiously withheld treatment to significantly exacerbate the child's illness.

### CONSIDERATION OF MCA IN CASE OF CHILD FATALITY

A significantly positive clinical history of a deceased child would feature 1 or more items listed in Box 292-1. If any of these factors is present, then MCA should be included in the differential diagnosis, along with possible genetic, metabolic, toxicologic, environmental, and other causes of death. These factors are not diagnostic criteria for MCA, but rather historical flags that should spur further investigation and an exhaustive autopsy.

The usefulness of the autopsy by a competent forensic pathologist as an investigative tool for determining cause and manner of death is obviously enhanced when it is performed in the most thorough manner. This would include toxicologic studies. A *routine toxicology study* may be inadequate and includes different tests at different laboratories. The laboratory should be asked to preserve the samples securely because they may be needed later for repeated studies or studies not originally considered. As with all children suspected of having been maltreated, a skeletal survey should be performed to look for fractures. Classic physical abuse injuries have been reported in victims of MCA. Additionally, microbiologic studies may be central to determining whether the child was the victim of inflicted microbial assault.

Homicidal suffocation deaths deserve further comment because they are still too commonly misdiagnosed as SIDS. If any significant history precedes death, then SIDS, by definition, is excluded. The current definition of SIDS is the unexpected death of an infant between 1 month and 1 year that remains unexplained after a *complete* review of the clinical history, death scene investigation, and autopsy. The physician must always be concerned when sudden death occurs in a child who had repeated apnea or acute life-threatening events before death, especially episodes that featured attacks beginning only in the presence of a single caregiver and, when the caregiver called someone to see the infant, the child was hypoxic (ie, cyanotic, gray, gasping, and limp). The physical findings of suffocation more commonly seen in adult victims (head and neck petechiae or bruising [or both], defensive marks) are almost always absent in young children. Intraalveolar hemosiderin found at autopsy may be a marker of past smothering, but this is not definitive.

### PERPETRATORS

What are the characteristics of the perpetrator of MCA? First, an important point to make is that no psychologic test can include or exclude perpetration of MCA. Second, no classic profile exists for a

**Table 292-1**    **Some Clinical Presentations of Medical Child Abuse<sup>a</sup>**

<b>SYSTEM</b>	<b>SYMPTOM, SIGN, LABORATORY FINDING OR DIAGNOSIS</b>
Head, eyes, ears, nose, throat, mouth	Bleeding from ears, nose, throat Conjunctivitis External otitis Hearing or speech impairment Nasal excoriation Nystagmus Otorrhea Parotitis or orbital cellulitis Tooth loss

### BOX 292-1 Review of Clinical History in a Dead Child: Circumstances Suggestive of Medical Child Abuse

- A history of repeated medical visits for unusual, poorly defined, unpredictable, or unresponsive illness, especially apnea and seizures.
  - Symptoms had never been confirmed to be witnessed at their starting moment by anyone other than a single caregiver.
  - A medical evaluation of the child revealed no organic abnormality that might *fully* account for the child's reported illness.
- Ill sibling of decedent, especially if the person was ill or is ill with chronic, poorly defined medical problems.
- Dead sibling of decedent or dead unrelated child in the same home as decedent, especially if any of the following is found:
  - Other child's death was signed out as sudden infant death syndrome (SIDS).
  - Death followed a poorly defined or chronic illness.
  - Cause of death was allegedly an illness that overwhelmingly is nonfatal in childhood.
  - Cause of death was related to poisoning or intoxication.
  - Cause of death was the result of an unusual accident.
  - Death followed a presumed illness that was either unsubstantiated or excluded at autopsy.
  - Explanation for the death was inadequate.
- Mother with chronic, poorly defined medical problems.

perpetrator. The perpetrator of MCA is usually the mother. The perpetrator sometimes has had nursing, medical, or paramedical training, perhaps never completed. The perpetrator may be married, single, or divorced; but, if married, then the relationship with the spouse, although perhaps seemingly satisfactory, is often shallow, with the husband at arm's length from the child's illnesses. In some instances, the spouse endorses the perpetrator's history of the child, even when it is proven definitively to have been untrue. Although the perpetrator was originally described as generally affable with medical and nursing staff, broader experience shows that the perpetrator may have a hostile, difficult, and demanding personality. Some perpetrators, in their roles as champions of their ill children, have had good success at enlisting the admiration of their communities; making useful, powerful, or lucrative contacts; or obtaining benefits consequent on the child's illness, including wish-fulfillment trips. Family medical histories are often unusual and unable to be confirmed.

The personality types, backgrounds, and motivations common to perpetrators of MCA are quite diverse. The perpetrators have been variably diagnosed psychiatrically as normal, depressed, borderline personality disorder, hysterical personality disorder,

narcissistic personality disorder, or various other personality disorders. MCA in the context of postpartum depression has also been reported. Only rarely is the mother deemed to be psychotic or delusional. Some reports cite a history of significant childhood maltreatment in these mothers, including physical and sexual abuse. In the past, the primary motivation has been described as the "use of a sick child as a vehicle to maintain and regulate a relationship with physicians and other medical personnel and later with other people seen as powerful." However, with the new terminology MCA, the motivation of the perpetrator is not the primary concern of the pediatrician.

No evidence whatsoever suggests that perpetrators of MCA are unaware of their actions. On the contrary, the planning and organization involved, the minute attention to secrecy, the fact that the assaults are committed without witnesses, and the carefully woven fabric of lies presented to the physician all suggest great awareness. The perpetration of MCA is volitional, and can be violent. The fact that the violence is encased in duplicity only hides, but does not diminish, its aggression.

### DIAGNOSTIC STRATEGIES

Failure to diagnose MCA means that a fundamentally healthy child and the child's siblings might be killed or irreversibly damaged. Conversely, the failure to exclude MCA may mean that necessary treatment is withheld from an ill child or the child is separated unnecessarily from the family. The single largest impediment to making a diagnosis of MCA is the failure to include it in the differential diagnosis. Once MCA is considered, the difficulty in diagnosis revolves around the dilemma of not wishing to expose the child to any more potential risk and yet needing reasonably definitive proof. This clinical judgment call is best made with the assistance of the multidisciplinary MCA team, which is described in detail later in this chapter. However, *early* involvement of the MCA multidisciplinary team is critical to providing safety for the patient. The diagnostic strategy must maximize diagnostic capability while minimizing risk to the child. When MCA is suspected, confirmation or elimination of the diagnosis may be undertaken through one of several strategies: records review, the search for evidence of illness fabrication, the search for evidence of an explanation other than MCA, and the separation of the child from the suspected perpetrator.

#### Records Review

The first diagnostic strategy is records review. This strategy evolves from the observation that the pivotal facts, although present in the medical record, are often obscured by the sheer volume of information. In other words, the crucial data is there, but is buried. Furthermore, the importance of a comprehensive overview of the child's medical presentation has been repeatedly overshadowed by the immediacy of the crises. Curiously, the more chronic and intractable the child's problem is, the less likely that the problem is given a fresh, comprehensive look. Records review may be the preferred diagnostic strategy because it carries little risk, and may be the only strategy

possible when the child is alive but is unavailable, when the symptoms and signs of fabrication are long gone, or when the child is dead.

For most pediatric patients, a thorough records review is straightforward, with records being relatively brief. However, a substantially different approach to records review is needed when MCA is suspected. This is a consequence of 3 typical features—the record is extensive, the legal implications are broad, and the stakes are high. Records often run to thousands of pages, sometimes from dozens of medical facilities. The physician may be called to testify in civil or criminal proceedings, where the hundreds of medical facts may be minutely tracked and challenged. Reviewers should take note of inconsistencies between the caretaker's history and the observed clinical findings. Furthermore, how do the laboratory results compare with the history given? A computerized system for data entry, storage, organization, and retrieval is often indispensable, and any of several commercially available database-management systems can be adapted for this purpose. While record review is occurring, consider notating pages to reference when talking with the larger MCA multidisciplinary team. The reviewer may also choose to assign page numbers to each page collected in the record so that documents can be found quickly. It may be most helpful to formulate a timeline based on the review, which again helps the multidisciplinary team to navigate a very complex and often confusing medical history.

Because the medical and nursing records are often complicated, using someone (or several people) experienced in both inpatient and outpatient pediatrics to review the records is best. In the process of the records review, compiling a cumulative dated list of factors, such as prescribed medications, operations, consultations, hospitalizations, diagnoses explored, diagnostic tests performed and their results, interventions attempted, and school days missed, is often helpful.

### Search for Evidence of Illness Fabrication

The second diagnostic strategy, the search for evidence of illness fabrication, may include tests such as toxicology studies if poisoning is suspected; blood group typing, subtyping, or DNA typing if contamination with exogenous blood is suspected; or hidden video monitoring if surreptitious suffocation is suspected. To a great extent, the physician must choose, or even design, the test, depending on the fabrication that is suspected. The search for evidence of illness fabrication must be carefully planned and executed. Depending on the situation, this search involves setting up the proper chain of evidence, preserving laboratory specimens, continuous monitoring and recording of video units with plans to intervene immediately and decisively if assault is seen, and establishing precise coordination with law enforcement and social services. The advantage of this diagnostic strategy is that, if positive evidence is uncovered and is reliable, it is more likely to be accepted as definitive, medically and legally. The disadvantage is the risk of continued harm to the child. If the test is negative, then distinguishing among absence of assault, failure to capture the assault, or a false-negative test is often impossible.

One method to search for evidence of illness fabrication is covert video monitoring. Useful clinical data may be accrued with videotaping, although the strategy is somewhat controversial. A video camera may be installed and linked to a monitoring and recording unit in a nearby room. Obviously, this type of system must be in place before the child's admission. Multiple cameras should be considered to take into account the possibility of assault in areas of the room that may not be visible from 1 camera's view. Continuous observation of the videotape by real-time monitoring is essential. As part of the multidisciplinary team, hospital security and the local police department would be aware of the videotaping and available as needed. The topic of diagnostic, covert video monitoring in the hospital has engendered some animated debate, with authors addressing the legal, ethical, and logistic aspects of videotaping. Some authors are concerned with the right to privacy of parents in the hospital, while other authors point out that the parental rights to privacy are abrogated when that parent is thought to be potentially harming the child. One investigator who videotaped mothers smothering their children noted that both children struggled violently until they lost consciousness. Considerable force was used to obstruct their airways, and this force was needed for at least 70 seconds before electroencephalographic changes occurred. Interestingly, in both cases, a soft garment was used to smother the children, and no marks were seen on the lips or around the nose. This reference also includes a description of typical findings on monitor tracings, "which may in the future proved to be pathognomonic for this type (smothering) of apnea." The authors recommend that hospitals collaborate with their legal team to develop a written policy if planning to use covert video monitoring, and, in some jurisdictions, a court order may be necessary.

### Search for an Explanation Other Than Medical Child Abuse

A third diagnostic strategy, the search for an explanation other than MCA, has often been applied extensively by the time MCA is suspected, but not necessarily exhaustively. This approach is best when no opportunity or diagnostic test exists that might capture evidence of commission or when the search for evidence of illness fabrication would expose the child to grave risk. The contending diagnoses on the differential should be those that are subject to definitive inclusion or exclusion. For example, if a child repeatedly presents to the hospital with apnea that begins only in the presence of the mother, then the disorders that might be causing the child's apnea, such as seizures or gastroesophageal reflux, can be definitively included or excluded. Positive test results must be carefully scrutinized to ensure that they are positive neither as a result of maternal contamination or intervention nor as a result of being *overcalled*. Certain gastrointestinal tests seem to be especially vulnerable to this problem, in particular gastrointestinal motility studies and esophageal pH probe studies. Nissen funduplications as well as the installation of central venous catheters are unnecessarily performed with distressing frequency in cases of MCA. Both procedures result in direct-line access

to the child and, therefore, the possibility of further intraluminal assaults on the child with feces, saliva, contaminated water, drugs, salt, air, and other substances. The advantage of this diagnostic strategy is that the gathering of diagnostic evidence does not involve exposing the child to the possibility of another assault. The disadvantage is that it can be time-consuming and expensive and can expose the patient to risks, including various diagnostic procedures or prolonged hospitalization.

### Separation of the Child from the Parent

The fourth diagnostic strategy, the separation of the child from the parent, may be very useful. In certain circumstances, this action carries the most diagnostic weight and is the least onerous. Having a baseline against which to compare the child's subsequent course during separation is important, whether the separation occurs in the hospital or in a foster home. The baseline is the well-documented history of the child's symptoms and signs as provided by the mother. Therefore, the only major change that is made in the child's care during the separation should be the presence of the caregiver. In some instances, the fabrication of illness causes irreversible medical problems. Other times, the fabrication of illness is piled onto an already existing illness. Only reversible conditions of the child can be expected to improve, and these only to the degree and at a rate that is consistent with the condition itself. The advantage of this diagnostic strategy is that it can be definitive without exposing the child to further risk. The disadvantage is that, if MCA is not present, then an ill child has been separated unnecessarily and perhaps harmfully from the mother, and correct diagnosis has been delayed. One way to minimize the possible disadvantages is to have supervised visits with the mother. The supervision must be constant and scrupulous, with no foods, medications, or candy permitted. This strategy may require a court order, as the perpetrator often will not willingly agree to a prolonged separation from the child.

The diagnostic strategies used to detect MCA in its most common presentations are outlined in Table 292-2. These diagnostic strategies will not fit every type of suspected event, and the physician must tailor the diagnostic strategy to the type of perpetration suspected. This effort may involve contacting colleagues in related fields so as to gather information or to seek help. Commonly, various diagnostic strategies must be combined. An excellent example of evaluating seizures by Barber and Davis serves as a useful reference that illustrates a comprehensive approach and can be adapted to many presentations.

## DIFFERENTIAL DIAGNOSIS

While all cases of MCA are different, there are some reemerging themes that are noteworthy and may help the physician attempting to identify MCA. These are listed in Box 292-2. It is critical to emphasize, however, that not all of these case characteristics may be present in a given case of suspected MCA and that many of these characteristics may be present in cases not involving MCA.

As already discussed, a thorough investigation for organic illness must be undertaken. An exhaustive differential diagnosis should be considered and addressed before concluding that indeed MCA is the most likely answer. However, the physician needs to resist putting the child through painful and invasive testing if the likelihood of organic disease is small and MCA seems the more likely diagnosis. Genuine illness and MCA often coexist. The discovery of a real illness in a child does not exclude MCA. The question then becomes, does this illness reasonably explain the severity, extent, and type of the child's symptoms and signs? Often in cases of MCA, the physician may repeatedly comment on the fact that the presentation is unlike anything he or she has ever observed in the past. Occasionally, the distinction between MCA and pathologic physician shopping, or magnification of a child's real but minimal illness for the parent's own psychologic or fiscal gain, may not be clear. For specific cases that seem to fall at the edges of the definition of MCA, one might ask, is this damaging or abusive to the child? Box 292-3 gives the differential diagnosis of persistent presentation.

## DIAGNOSTIC CRITERIA

When MCA is suspected, the strength of the medical findings needed to establish a diagnosis may extend from weak to definitive. Thus, different degrees of diagnostic conviction may be found, not only from case to case, but also within a case, depending on the stage of the assessment. One can, therefore, attempt to categorize the findings as definitive, possible, uncertain, and definitely not MCA. Below are the diagnostic criteria, reprinted and modified from Rosenberg, that must be present, and when taken collectively, are sufficient for diagnosis.

### Definitive Diagnosis

The definitive diagnosis of MCA can be made in by inclusion or exclusion. A diagnosis by inclusion is supported by evidence of commission. For example, if a mother smothers the child who she had previously and repeatedly presented for apnea, and if her act were captured with covert videotaping in the hospital, then the definitive diagnosis of MCA would be by inclusion.

Box 292-4 lists the criteria for the definitive diagnosis by inclusion of MCA.

A diagnosis by exclusion is one in which all other possible explanations for the child's condition have been considered and excluded. For example, if a child who repeatedly presents with apnea while in one person's care that results in observable clinical compromise is observed in the hospital and has no evidence of apnea, and all other possible medical conditions have been investigated and excluded, then the definitive diagnosis of MCA is made by exclusion. Box 292-5 lists the criteria for the definitive diagnosis by exclusion of MCA.

### Possible Diagnosis

A possible diagnosis of MCA is 1 among several likely diagnoses. Box 292-6 lists the criteria for the possible diagnosis of MCA. Medical professionals are legally

Table 292-2

## Symptoms, Methods of Fabricating Illness, and Corresponding Diagnostic Strategies in Medical Child Abuse

PRESENTATION	METHOD OF SIMULATION OR PRODUCTION OR BOTH	METHOD OF DIAGNOSIS
Apnea	Manual suffocation	Video monitoring Implantable ECG recorder Diagnosis by exclusion Patient with pinch marks on nose Witnessed Toxicology of gastric fluid, blood, urine or IV fluid
Seizures	Poisoning: tricyclic antidepressants, hydrocarbons Fabrication Poisoning: phenothiazines, hydrocarbons, sulfonyleurea, tricyclic antidepressants Salt Suffocation or carotid sinus pressure	Diagnosis by exclusion Toxicology of gastric fluid, blood, urine or IV fluid Serum and urine sodium concentrations Witnessed; forensic photographs of pressure points
Diarrhea	Phenolphthalein or other laxative poisoning Salt poisoning	Stool or diaper positive Sodium concentrations of serum, urine or gastric contents; assay of formula
Vomiting	Emetic poisoning Injection of air into gastrostomy tube Fabrication	Urine for drug Video monitoring Hospital observation
CNS depression	Poisoning: diphenoxylate and atropine (Lomotil), insulin, clonidine, barbiturates or narcotics, benzodiazepines, aspirin, diphenhydramine, tricyclic antidepressants, acetaminophen, hydrocarbons, chlordiazepoxide, chloral hydrate, antiepileptics	Toxicology of blood, gastric contents, urine, IV fluid, hair; analysis of insulin type; video monitoring
Bleeding	Rodenticide (warfarin) poisoning Phenolphthalein poisoning Exogenous blood applied	Toxicology Diaper positive Blood group antigen profiling; DNA typing; <sup>51</sup> Cr labeling of erythrocytes Witnessed
Rash	Exsanguination of child Addition of substances (paint, cocoa, dyes) Drug poisoning Scratching	Testing; Washing Assay Diagnosis of exclusion
Fever	Caustics applied/painting skin Contamination with infected material (saliva, feces, dirt) Falsifying temperature Falsifying chart	Assay or wash off Witnessed; type of organism growing from infected sites Careful charting, rechecking (especially rectal temperature or urine for core body temperature) Careful charting; Duplication (ghost record) of temperature chart at nursing station

CNS, central nervous system; ECG, electrocardiographic; IV, intravenous.

From Rosenberg DA. Web of deceit: a literature review of Münchausen syndrome by proxy. *Child Abuse Negl.* 1987;11:547–563, with permission from Elsevier.

mandated to report child abuse to the local authority when they have a reasonable suspicion of it. *Reasonable suspicion* is not a term of art in medicine, but rather roughly translates into the set of diagnostic criteria here noted as a possible diagnosis.

### Inconclusive Determination: Cannot Know

Rather than increasing the weight of medical evidence in support of a diagnosis of MCA, accumulating data may instead diminish its likelihood. Medical criteria for inconclusive findings (that is, for MCA being indeterminate) are, therefore, articulated here. *Cannot know* means that, although the collection of data is complete, the data are insufficient to determine the diagnosis. The investigator can confidently neither

establish nor eliminate MCA as the diagnosis. *Cannot know* differs from possible diagnosis because implicit in a *cannot know* determination is the assertion that all relevant and available strategies for diagnosis have been exhausted. This position is in contrast to a possible diagnosis, in which an expectation of further diagnostic strategy can be found. Box 292-7 lists the criteria for an inconclusive (*cannot know*) determination.

### Definitely Not

*Definitely not* MCA means that the diagnosis can be absolutely eliminated because a wholly credible alternative explanation is at hand. To allow degrees of certainty within this diagnostic option, the physician might want to use some kind of qualifier, for example,

**BOX 292-2 Factors That May Be Present in Cases of Medical Child Abuse**

- Illness is multisystemic, prolonged, unusual, or rare.
- Symptoms and laboratory results are incongruent with patient's presentation.
- Symptoms disappear or diminish when caregiver is absent.
- Caregiver has extensive medical knowledge or background.
- Caregiver encourages medical staff to perform numerous tests and studies.
- Caregiver is not reassured by patient progress or seemingly reassuring results.
- Patient has multiple allergies to foods or medications.
- Patient has poor response to standard therapies (eg, continued report of seizures at home after multiple anticonvulsants).
- Patient unable to tolerate treatment (eg, frequent vomiting, rash, pain).
- Often caregiver's spouse is emotionally or physically absent/distant.
- Family history may include complex medical diagnoses of parent/sibling or diagnoses that are difficult to confirm (pregnancy complications, spontaneous abortion, sudden infant death syndrome [SIDS], etc).
- Caregiver is sometimes admired for overwhelming devotion to patient's care or viewed as the model parent.

**BOX 292-3 Differential Diagnosis of Persistent Presentation**

- Organic illness
- Anxious parent
- Developmentally delayed parent
- Vulnerable child syndrome
- Psychogenic illness
- Medical child abuse
- Münchausen syndrome

*probably not MCA. Probably not MCA* is about the same as saying that, in all likelihood, an alternative explanation is at hand. The fact that diagnostic criteria for the exclusion of MCA are included means that, as with other pediatric disorders, inevitably, more suspected cases than actual cases exist. Recognizing this situation means also recognizing the need for the swiftest and most decisive diagnostic test, but one in which the risk to the child does not seem to be excessive. Extreme care must be taken not to overdiagnose MCA or to be married to the diagnosis in the absence of sufficient evidence. Cases of misdiagnosed MCA are a real tragedy for the family and child. Box 292-8 lists the criteria for excluding the diagnosis of MCA.

**BOX 292-4 Medical Child Abuse: Criteria for a Definitive Diagnosis by Inclusion**

1. Child has been repeatedly presented for medical care.  
AND
2. Test or event is positive for tampering with child or with child's medical situation.  
AND
3. Positivity of test or event is not credibly the result of test error or misinterpretation or of miscommunication or specimen mishandling.  
AND
4. No explanation for the positive test or event other than illness falsification is medically possible.  
AND
5. No findings credibly exclude illness falsification.

From Rosenberg DA. Münchausen syndrome by proxy: medical diagnostic criteria. *Child Abuse Negl.* 2003;27:421–430, with permission from Elsevier.

**BOX 292-5 Medical Child Abuse: Criteria for a Definitive Diagnosis by Exclusion**

1. Child has been repeatedly presented for medical care.  
AND
2. All diagnoses other than illness falsification have been credibly eliminated so that
  - A. If the child is alive, then the competing diagnoses are those that took into account the child's major medical findings, and that account for the entirety of the child's presentation.  
OR
  - B. If the child is alive, then separation of the child from the alleged perpetrator results in resolution of the child's reversible medical problems, in accordance with their degree and speed of reversibility. No variable other than the separation can logically and fully account for the child's improvement.  
OR
  - C. If the child is dead, then autopsy examination does not reveal a cause of death that is credibly accidental, natural, or suicidal.  
AND
3. No findings credibly exclude illness falsification.

From Rosenberg DA. Münchausen syndrome by proxy: medical diagnostic criteria. *Child Abuse Negl.* 2003;27:421–430, with permission from Elsevier.

**INTERVENTION**

A list of treatment directives for all cases in which MCA is suspected is not possible. However, the practicing pediatrician and accompanying multidisciplinary team may find the following considerations useful:

1. **Optimally, the child should be protected while definitive data is collected to either include or**

**BOX 292-6 Medical Child Abuse: Criteria for Possible Diagnosis**

1. Child has been repeatedly presented for medical care.  
AND
2. Test or event is presumptively positive for tampering with child or with child's medical situation. No other explanation is readily apparent. No findings seem to exclude illness falsification.  
OR  
Child has a condition that cannot be fully explained medically, despite a respectable initial evaluation, at least. Cogent hypothesis suggests a faked medical condition. No findings seem to exclude illness falsification.

From Rosenberg DA. Münchausen syndrome by proxy: medical diagnostic criteria. *Child Abuse Negl.* 2003;27:421–430, with permission from Elsevier.

**BOX 292-7 Medical Child Abuse: Criteria for Inconclusive Determination**

1. Child has been repeatedly presented for medical care.  
AND
2. The relevant and available information has been reviewed, the child has been appropriately evaluated, or both.  
AND
3. Physician is left with a differential diagnosis, rather than a single diagnosis.  
AND
4. Conclusively affirming 1 diagnosis is not possible.  
AND
5. It is not possible to conclusively exclude all but 1 diagnosis on the differential diagnosis.

From Rosenberg DA. Münchausen syndrome by proxy: medical diagnostic criteria. *Child Abuse Negl.* 2003;27:421–430, with permission from Elsevier.

**BOX 292-8 Medical Child Abuse: Criteria for Excluding the Diagnosis**

1. Child has been repeatedly presented for medical care.  
AND
2. What had seemed to be possible falsification of illness has been wholly and credibly accounted for in some other way.

From Rosenberg DA. Münchausen syndrome by proxy: medical diagnostic criteria. *Child Abuse Negl.* 2003;27:421–430, with permission from Elsevier.

**exclude the diagnosis.** Professionals must weigh the eventual usefulness of this data against the possibility of a mishap occurring to the child during the data-collection process. When further diagnostic procedures place the child at risk, the protection of the child is always paramount.

2. **A multidisciplinary team should be involved early in the investigation.** The members of the MCA team should include the physician, the bedside and supervising nurses, the hospital social worker, and the subspecialist physicians involved in the patient's care. The bedside nurse and the head nurse often have extensive knowledge of the patient and family from prior hospitalizations. The primary care nurse often becomes responsible for important items such as documentation and chain of evidence of specimens. The county department of social services should also be contacted so that the medical concerns can be clearly explained. Early and clear communication with this team member is critical so that the team member can assist in protecting the child as well as obtain emergency custody if necessary. The hospital attorney, hospital security, risk management, and hospital administrators and public relations personnel need to be involved. If an event results in an arrest, the hospital will almost certainly be contacted by news media. The supervisor of the social workers involved should be included from the start. Police and other law-enforcement personnel should also be involved early. Should an episode of intentional infliction of harm come to light during videotaping, the police generally prefer to have prior knowledge of the case and may want to be prepared with an arrest warrant. Additionally, psychiatrists or psychologists can help to evaluate the caregiver and evaluate the child from a developmental and psychologic perspective, as well as provide support after confrontation of the family with the suspected diagnosis. The mother, who is generally the alleged perpetrator, is at increased risk for suicide after such a confrontation. It is worth stating that the mental health specialist evaluating the caregiver would optimally have experience with MCA cases, because the caregiver is often manipulative and persuasive. The multidisciplinary child-protection team is under no obligation to include the mother's attorney (if she has engaged one) or any other professionals who may divulge either the diagnostic strategies planned or the content of the proceedings to the family.
3. **Medical records should be reviewed in a comprehensive and organized fashion.** The physician should attempt to identify certain patterns, such as intractable vomiting or recurrent apnea, that have never been witnessed by anyone other than the caregiver. The physician should also identify any discrepancies between the caregiver's history and documented laboratory and physical findings.
4. **All medical records of all siblings must be reviewed, including autopsy reports and death certificates.** The process of obtaining these records often requires considerable effort, but they are vital. Neither police summaries nor social work records are sufficient.
5. **The parents' medical, educational, criminal, and work history should be reviewed, if possible.** While other members of the multidisciplinary team, such as law enforcement and CPS investigators, bear much of this responsibility, the treating physician can make recommendations to the

investigators responsible for gathering such information. This is particularly helpful if the parent claims various illnesses or medical education background.

6. **Several methods may be used, singly or in combination, to gain access to records.** In some instances, signed parental consent to obtain the records is possible. Otherwise, the attorneys on the multidisciplinary team may advise canvassing the area with subpoenas or requesting court-ordered discovery of records.
7. **Presentation of the review of records to the multidisciplinary team should include, as briefly as possible, a chronologic review followed by a review of discrepancies, if any.** How does the mother's history compare with the observed clinical findings in the child? How do the laboratory test results compare with the given histories (eg, are drug levels continually subtherapeutic or toxic with a history of absolute compliance)?
8. **Interviewing other family members regarding the child's illness and the mother's veracity can be very helpful.**
9. **Recommending out-of-home placement for the child is prudent.** This measure ensures protection of the child and a diagnostic period of separation to see how the child's health fares. If, up to this point, a mother has only simulated but not produced illness, there is no guarantee that she will not do something more harmful to the child in the future. *Simulators* may become *producers* of illness. Confrontation of the parent with the news of the suspected diagnosis does not, in and of itself, ensure safety for the child. The reader is cautioned in particular about the dangers of placing the child with a family member or friend. This situation is always difficult because, for the child, the easiest transition may be to an aunt or grandmother, but the perpetrator may have access to the child, despite the relative's or the friend's promises to the contrary. This decision places the child at potential dire risk. The perpetrator only rarely admits to MCA; however, curiously, she will more often agree to voluntary services as long as the court is not involved and a dependency petition is not filed. No success with this approach has been reported. Experience has shown that court-ordered intervention is necessary for any hope of successful protection of the child.
10. **If the child is to remain in the hospital for a time, then a medically experienced person must supervise all visits with all family members to ensure that no one is tampering with the child's medical care.** In some instances, the best course of action is to ask the court for a short (ie, 10-day to 2-week) period of hospitalization with only supervised parental visits as a diagnostic trial to determine if the child's symptoms floridly persist. If they do not, then concern about MCA is heightened. If they do, then the court should be asked to vacate the order and turn attention to a fresh look for an organic diagnosis. This approach is useful only if the child's symptoms and signs, if induced, would reasonably be

expected to abate rather quickly in the absence of ongoing assault.

11. **Recommending out-of-home placement of siblings is prudent because they may become the next targets if they remain in the home.** All siblings must at least have court-ordered medical evaluations and review of records.
12. **Once the child is in foster care, the health status of the child must be monitored and documented closely by the same physicians.** Although having the original physician or set of physicians involved in the child's ongoing care is often optimal, this arrangement is sometimes not practical for reasons of geographic circumstances. Continued surveillance is critical and should include ongoing assessment of the child's mental and behavioral health, school functioning, and safety.
13. **Deciding when to send the child home is difficult.** If the diagnosis is indeed MCA, then the same guidelines that apply to other forms of child abuse and neglect should be applied in consideration of when to send the child home. In other words, the perpetrator must acknowledge that she committed these acts, she must have some insight into the reasons for it, and she must provide reasonable assurance that sufficient change has occurred to ensure the safety of the child. Very little information is available on family reunification after psychiatric intervention. In 1 study, family reunification was thought to be feasible in certain cases, but the authors cautioned that long-term follow-up is necessary to monitor the safety of the child and assess whether the perpetrator's mental health has deteriorated. The mental health professional charged with providing the initial assessment and ongoing therapy for the mother should have experience and expertise in MCA. The mother's therapist should discuss with the court and the child-protection team specific issues that concern the safety of the child. If the mother and the psychiatrist insist that all the information is privileged, then the court has no way to determine that the children will be safe at home, and other permanent arrangements must be made for them.
14. **Even if the children are removed permanently and parental rights are terminated, subsequent children born to the mother are at high risk of being targets of MCA.** No formal method is available to keep track of the mother's pregnancies; but every effort must be made to protect future children.

## LEGAL CONSIDERATIONS

Anytime child abuse is suspected, a report to investigating agencies, including CPS and law enforcement, by the concerned physician is mandatory. It is important to emphasize that MCA is no exception. When presenting a case of MCA to the civil or juvenile court, some strategies of presentation may assist in coming to a conclusion. Despite the many hours spent in reviewing records and making an extensive chronologic compilation of the child's medical history, presentation of the information in long, narrative form often

confuses, rather than elucidates, the material. A short summary is often better. The physician may then be asked to clarify or expand on particular events. Graphs and charts that are clearly readable are helpful. For example, a growth chart may show that the child consistently gains weight in the hospital but loses weight at home. A histogram may show the number of apnea episodes that originated in the presence of the mother compared with the number that originated in the presence of the nursing staff. Cases typically involve conflicting medical opinions, and the parents usually have medical experts testify on their behalf. A clear grasp of the medical and epidemiologic evidence and a professional, nonadversarial attitude is always best. Criminal court proceedings undertaken against the perpetrator are still relatively rare, even in homicidal MCA.

In a courtroom or out, physicians are not required to translate the degree of diagnostic conviction into a legal equivalent. Terms such as *probable cause*, *reasonable suspicion*, *preponderance of the evidence*, *clear and convincing evidence*, and *evidence beyond a reasonable doubt* have a specific meaning in the law. If asked whether the evidence conforms to any of these burdens, or if a reasonable degree of medical certainty exists about the diagnosis (a popular question), the medical language that is meaningful to the physician should be used and distilled into lay terms that best embody the physician's meaning.

The physician should be alert to attempted manipulation by lawyers. The physician should not be badgered, flattered, or lulled into changing her opinion. The purpose of the medical witness is to provide a balanced, thorough, and comprehensible interpretation of the medical data. An important point to remember is that practicing attorneys have jobs that are different from those of physicians.

A diagnosis of MCA may have been based, at least in part, on the information that the physician reviewed in records. The physician may be asked if the professional opinion would change given different or additional information, to which the most accurate answer is often that the possibility exists but, absent the information and the time to think it over, the likelihood of that possibility is impossible to determine. It is the court's, not the physician's job to make a final legal determination.

## PHYSICIANS AND MEDICAL CHILD ABUSE

As is well outlined by Donald and Jureidini, the health care system and physician may bear some responsibility for contributing to morbidity in MCA cases. This syndrome has been abstractly characterized as a "dance," in which the physician unknowingly plays a crucial role in perpetuating the illusion of disease. Physicians do not expect a false history. Young physicians are worried by the cautionary tales of missed diagnoses and seasoned physicians are haunted by their own experiences of misdiagnosis. Most physicians want to be thorough while still operating in a very busy primary care practice. What used to be known as *defensive medicine* has now become almost mainstream medicine. Little time exists for pondering.

A well-founded fear of litigation pervades the practice of medicine. It is no longer uncommon for the perpetrator of MCA to make false allegations of malpractice to professional or licensing bodies, or to sue the physician or hospital on a number of pretexts, including defamation of character, malicious reporting, malpractice, wrongful detention of the child, or wrongful death. Additionally, personal vulnerabilities of some physicians may make it difficult for them to say, "I don't know." The interplay between primary care physicians and subspecialists may impede the correct diagnosis. As mentioned previously, a very fragmented system of medical care often develops as more and more subspecialists become involved. Small pieces of the puzzle are held by different physicians, while no one truly has a comprehensive view of the patient's condition. Involving a child abuse physician may be helpful in this situation, to take the responsibility of the MCA diagnosis off the other subspecialists and the primary care physician.

## CONCLUSION

Medical child abuse by any name is a serious form of child abuse. Multiple terms are used when making this diagnosis, however, MCA is the term that the authors of this chapter are recommending because of its ability to clearly define the presence of abuse, while at the same time shifting the focus from the parent or caregiver to the child. A thorough evaluation, although always necessary in child abuse investigations, is critical in evaluating possible MCA. This includes not only a complete history and physical examination, but also a detailed and exhaustive review of the medical record. Care should be taken throughout this process not to expose the child to additional risk or unnecessary tests. A multidisciplinary team is mandatory for proper evaluation and may include individuals who are not typically part of the child protection team, such as attorneys, law enforcement representatives, and mental health specialists. The process of diagnosis is time-consuming and difficult, and requires continued communication among all parties. Involvement of a child abuse specialist, if possible, is helpful. Education of physicians and child protection agencies is paramount so that this diagnosis can be considered and appropriately pursued.

## ACKNOWLEDGMENT

The authors wish to acknowledge the contributions of Donna Andrea Rosenberg, MD as the author of the original version of this chapter.

## Chapter 293

# MUSCULAR DYSTROPHY

*Richard T. Moxley III, MD; Emma Ciafaloni, MD*

The muscular dystrophies are a group of slowly progressive, inherited diseases with specific patterns of muscle wasting and weakness. These disorders occur infrequently in childhood; a busy pediatrician may care for only a few patients during a career. However, breakthroughs in molecular biology have provided direct genetic tests for these diseases and have created opportunities to suggest and coordinate family counseling and prenatal testing. The primary care physician plays an important role in facilitating early diagnosis and referral to a neuromuscular specialist, helping with genetic testing, and monitoring patients for the pulmonary, cardiac, and orthopaedic complications of these muscular dystrophies. Duchenne dystrophy is the most common muscular dystrophy in childhood, and major advances have been made in its diagnosis and treatment. For these reasons, this chapter focuses on Duchenne dystrophy, although other muscular dystrophies that occur in childhood are also addressed.

## DUCHENNE DYSTROPHY

### Definition

Duchenne dystrophy is a slowly progressive muscle-wasting disease marked by symptoms that usually develop before age 5 years. Early in its course, Duchenne dystrophy affects the proximal hip and shoulder girdle muscles, as well as the anterior neck and abdominal muscles. The symptoms arise from an absence or extreme deficiency of a large cytoskeletal protein, dystrophin, that attaches to the inner surface of the muscle fiber membrane as a part of a complex of glycoproteins. Dystrophin is also part of the inner membrane structure of smooth and cardiac muscle and of certain cells in the central nervous system, and is found in specialized connective tissues such as the myotendinous junctions. This distribution of dystrophin corresponds closely to tissues that have major clinical manifestations in Duchenne dystrophy, such as cardiomyopathy and autism-like features.

The mechanism by which dystrophin deficiency causes dysfunction in some muscle groups while sparing others is a puzzle. Some experts have speculated that dystrophin protects and strengthens the muscle membrane to withstand the stresses of repeated muscle contractions and that it helps prevent excessive influx of calcium to speed the effective repair of tears in the muscle membrane that occur with vigorous exercise. However, this question still remains: Why do heavily used muscles, such as the extraocular and laryngeal muscles or the gastrocnemius muscles, maintain their strength despite the lack of dystrophin? Some experts speculate that upregulation of another large cytoskeletal protein, such as utrophin, can help maintain muscle function. In mdx mice, overexpression

of utrophin can compensate for the absence of dystrophin, restoring normal function, but no effective upregulation therapy is yet available for clinical use in Duchenne dystrophy. MDX mice are the most popular animal model of Duchenne muscular dystrophy caused by a point mutation in the mouse dystrophin gene with findings not identical to human Duchenne dystrophy. Further research is in progress to clarify the role that such alternative proteins may play in rescuing muscle fibers from destruction in diseases involving dystrophin deficiency. The findings will help in developing new strategies for treatment.

### Genetics

Duchenne dystrophy is an X-linked disease, therefore affecting male newborns only. Female manifesting carriers are very rare. The gene for dystrophin in the *Xp21* region is among the largest known, occupying 1% of the entire X chromosome. It contains 79 exons, and 5 different promoters control production of isoforms that are cell-type specific (eg, muscle, cerebral cortex, Purkinje, glial, Schwann cells). Large deletions occur in approximately 60% to 70% of cases of Duchenne dystrophy and in an even higher percentage of cases of Becker dystrophy (a later-onset X-linked dystrophy also caused by a deficiency of milder dystrophin). In addition to large deletions, duplications occur in about 5% to 10% of patients, and single nucleotide mutations occur in approximately 25% to 35% of patients who have Duchenne dystrophy and 15% of those who have Becker dystrophy. No consistent relationship has been established between clinical severity (Duchenne dystrophy vs the milder Becker dystrophy) and the size of the gene mutation. However, mutations that alter the reading frame (ie, out-of-frame-mutations) result in complete lack of dystrophin and more severe phenotype, while in-frame mutations allow for partial transcription of smaller size dystrophin and a milder phenotype. Deletion of the first muscle exon and the adjoining muscle promoter region seems to produce phenotypes that have either mild muscle involvement or that have mild muscle involvement but severe cardiomyopathy.

### Clinical Presentation and Differential Diagnosis

As outlined in Table 293-1, Duchenne dystrophy typically occurs in patients between 2 and 4 years of age. Parents notice weakness of forward head flexion that persists beyond infancy, accompanied by slowed motor development. Patients demonstrate progressive gluteal and shoulder girdle muscular weakness, leading to a widened stance, lumbar lordosis, forward thrusting of the abdomen, and toe walking. Patients never run normally and usually put their hands on their knees to rise from the floor (Gower's maneuver; Figure 293-1) and to assist in climbing steps. These patients have difficulty keeping up with their peers, a difficulty that becomes more apparent as they enter preschool and kindergarten. The teacher often observes a problem and helps the parents decide to bring

the child to the pediatrician. The child is not just normally clumsy, and poor motivation is not the cause for the child's tendency to fall easily and complain of tiredness and calf cramps. Primary care physicians must be sensitive to the protean nature of these early complaints in Duchenne dystrophy, including toe walking, difficulty with stair climbing, and language delay.

Because many patients with Duchenne dystrophy have mild cognitive deficits and language delay, the child may seem to be intellectually disabled, and the pediatrician may not consider Duchenne dystrophy or ordering a creatine kinase (CK) screen. Because of the gradual development of hip and knee extensor weakness in middle childhood, patients often toe-walk to use the power of the gastrocnemius to help stabilize knee extension. Reliance on the calf muscles during ambulation contributes to the typical hypertrophy of the calf muscles. However, the pattern of walking in these children and the presence of mild cognitive deficits can sometimes lead to the incorrect diagnosis of cerebral palsy, delaying correct diagnosis and effective treatment.

A complete history almost always distinguishes patients who have Duchenne dystrophy from those who have other conditions that cause proximal weakness without sensory findings in childhood. Hypothyroidism usually has more generalized symptoms, as does carnitine deficiency. Blood tests can exclude these 2 conditions from the differential diagnosis. Neither of these conditions causes the high CK levels that occur in Duchenne dystrophy. Variants of spinal muscular atrophy and early-onset cases of limb girdle muscular dystrophies (LGMD) may resemble Duchenne dystrophy. Hypertrophy of the calf muscles may be a feature of Duchenne dystrophy or childhood-onset LGMD. Spinal muscular atrophy produces no increase or only a mild increase in CK. As outlined in Table 293-1 and Figure 293-2, DNA analyses and, only rarely, muscle biopsy are the appropriate diagnostic tests to establish the diagnosis of Duchenne dystrophy. If muscle biopsy is needed, then the findings will help distinguish among many of the autosomal-dominant and autosomal-recessive forms of LGMD that sometimes have a close clinical similarity to Duchenne dystrophy.

Other, more acute conditions such as childhood myasthenia gravis and inflammatory myopathy are not usually confused with Duchenne dystrophy. The more rapid evolution of weakness, along with the presence of ptosis, ophthalmoparesis, and facial weakness distinguish myasthenia gravis from Duchenne dystrophy. The more generalized weakness that occurs in inflammatory myopathy, along with a skin rash, helps separate these patients from those who have Duchenne dystrophy. In rare cases, chronic demyelinating polyneuropathy may be confused with Duchenne dystrophy, but the absence of ankle reflexes, more generalized weakness, a more rapid course, the lack of marked increase of CK, and abnormally slowed nerve conduction identify these patients.

The combination of a complete history and judicious use of the tests outlined in Table 293-1 will establish the diagnosis of Duchenne dystrophy in virtually all cases. In rare cases, a floppy infant will have a markedly increased serum CK level, and physicians will wonder

whether the baby has a variant of Duchenne dystrophy. Newborns or infants who have Duchenne dystrophy also have a marked increase in CK, but they are not floppy. Some other problem must be present as well if a patient with Duchenne dystrophy is floppy. Floppy infants who have high CK levels usually do not have Duchenne dystrophy. If such a patient does not have an infectious, toxic, or metabolic disorder that causes muscle destruction to account for the marked increase of serum CK level, then the child usually has one of the 2 relatively rare childhood muscular dystrophies noted in Table 293-1 and Table 293-2. These diseases are the severe childhood autosomal-recessive forms of congenital muscular dystrophy. The workup and treatment of these disorders are summarized in Table 293-1 and Table 293-2. Certain congenital myopathies may be marked by floppiness, but these infants do not have significantly increased CK levels.

### Evaluation

Once the physician suspects the diagnosis of Duchenne (or Becker) dystrophy, the serum CK should be measured promptly to avoid diagnostic delay. A marked increase (10-fold or more above normal) in a male patient excludes most other disorders and strongly suggests the diagnosis of Duchenne dystrophy. At this point, discussing with the parents the possibility that the child has a muscular dystrophy is appropriate. However, the physician should refer the patient to a neurologist skilled in the care of patients with neuromuscular disease for confirmatory DNA testing. At present, DNA testing for duplication/deletion in the dystrophin gene can confirm the diagnosis in about 60% to 75% of cases. In the remaining patients, DNA sequencing can further identify up to 95% of cases. The remainder of patients with negative DNA testing will need a muscle biopsy for dystrophin western blot to confirm the diagnosis. A detailed discussion of the natural history of Duchenne dystrophy or a discussion of the procedures for screening the mother and other at-risk family members for carrier status at this time is premature and can be postponed. This discussion is best initiated after the neurologic consultation and after specific diagnostic information is available (see Table 293-1 and Figure 293-2). The neuromuscular specialist should take responsibility for the initial description of the course of Duchenne dystrophy and discuss the treatment options. Figure 293-2 provides a flowchart that neurologists typically follow to arrive at a diagnosis of Duchenne dystrophy.

A continuously updated list of laboratories and tests available for the genetic diagnosis of Duchenne muscular dystrophy can be found at GeneTests ([www.genetests.org](http://www.genetests.org)).

### Management Supportive Care

The overall goals in managing children who have Duchenne dystrophy are to maintain ambulation for as long as possible, to optimize the development of the child's cognitive abilities, and to anticipate the occurrence of complications such as excessive weight gain,

**Table 293-1** Symptoms, Genetics, and Diagnostic Tests for Muscular Dystrophies in Childhood

CHARACTERISTIC	DUCHENNE DYSTROPHY	BECKER DYSTROPHY	MYOTONIC DYSTROPHY
Age at onset	Before age 5, typically at 2–4 yr	After age 5; can begin in adult life	Infancy, childhood, or adult life
Initial symptoms	Cannot run or keep up with peers; can take only 1 step at a time	Fatigue or marked thigh weakness; trouble climbing steps; occasional calf or thigh cramps; patients can ambulate beyond age 15 yr	Congenital form—floppy infant, poor suck, weak respiratory effort, talipes; childhood form—bifacial weakness, slurred speech, impaired hearing, intellectual disability
Incidence	1:3,500 of male births	1:35,000 of male births	1:8,000 of all births
Genetics	X-linked recessive/ <i>XP21</i> region of gene for dystrophin	X-linked recessive/ <i>XP21</i> region of gene for dystrophin	Autosomal-dominant chromosome 19
Gene lesion	Mutation in the dystrophin gene	Marked deficiency of dystrophin	Abnormal expansion of CTG trinucleotide repeat in 3' nontranslated region of a gene coding for a serine/threonine kinase
Serum creatine phosphokinase	10× above normal	5–10× above normal	Normal or 2–5× above normal
Electrodiagnostic testing	Normal nerve conductions; myopathic EMG	Normal nerve conductions; mildly myopathic EMG	Normal nerve conductions; myotonic discharges present in children and adults, but often absent in infants (EMG should be performed on the mother)
Muscle biopsy	Active myopathy, absence of dystrophin, severe reduction in dystrophin-associated proteins	Moderately active myopathy, absence or deficiency of dystrophin, reduction in dystrophin-associated proteins	Increased central nuclei atrophy of type I fibers, ringbinden, and subsarcolemma masses
Leukocyte DNA testing	If suspicion is high, perform DNA screening first. If leukocyte DNA testing is negative, perform muscle biopsy. DNA is screened for deletions and duplications (60%–70% have them); if deletion/duplication is found, deletion tests are performed in at-risk family members; if no deletion is found, DNA sequencing for point mutation should be performed	Same as Duchenne dystrophy	If this diagnosis is suspected, a Southern blot analysis is performed to identify an abnormally large expansion of CTG repeats in the gene; if the Southern blot test is normal, a polymerase chain reaction test is done to search for smaller expansion of the repeat; most childhood cases show abnormal CTG repeat enlargements (eg, 500–4,000 repeats), whereas normal alleles have 5–30 repeats

AR-EDMD, autosomal dominant Emery-Dreifuss muscular dystrophy; CMD, congenital muscular dystrophy; CTG, cytosine-thymine-guanine; EDMD, Emery-Dreifuss muscular dystrophy; EMG, electromyography

**FACIOSCAPULOHUMERAL DYSTROPHY**

Rare cases in infancy, occasionally in childhood, usually in adult life  
 Congenital form (rare)—bifacial weakness, sometimes ophthalmoparesis, occasionally floppy, deafness; childhood form (more common)—mild facial weakness and weakness of scapular fixator muscles  
 1:20,000 of all births  
 Autosomal dominant; most cases localize to chromosome 4

Deletion of a variable quantity of 3.3-kb tandem repeats at 4q35 and abnormal methylation of the D4Z4 region

2–5× above normal

Normal nerve conductions; EMG occasionally myopathic, often within normal limits

Nonspecific myopathy; up to 30% have mononuclear inflammation

DNA analysis available to identify the 3.3-kb deletions noted above; should perform before obtaining muscle biopsy if clinical suspicion is high

**CONGENITAL MUSCULAR DYSTROPHIES (CMDs)**

Infancy; before age 2

Floppy infant; joint contractures, spinal rigidity, global developmental delay

1:21,500  
 Autosomal recessive except for 6-deficient CMD, which can be autosomal recessive or dominant; and LMNA-related CMD, which is inherited in an autosomal-dominant manner

Defects of proteins in the basement membrane (laminin alpha-2 [ie, merosin-deficient CMD]); Defects of proteins in the extracellular matrix: collagen VI-deficient CMD (Ulrich CMD); Defects of glycosyltransferase enzymes resulting in abnormal glycosylation of alpha-dystroglycan (Walker-Warburg syndrome; Fukuyama CMD); Defects of proteins of the endoplasmic reticulum: selenoprotein N1 (rigid spine syndrome) Defects of nuclear envelope proteins: lamin A/C and nesprin-1  
 >10× above normal

Normal nerve conductions; electromyography myopathic

Dystrophic changes with adipose and connective tissue replacement, and often prominent inflammatory infiltrates

*LAMA2*; *Col6A1-A2-A3*; *POMT1*; *POMT2*; *FKTN*; *FKRP*; *LARGE*; *POMGNT1*; *SEPN1*; *LMNA*; *SYNE1*

**EMERY-DREIFUSS MUSCULAR DYSTROPHY (EDMD)**

Middle to late childhood

Mild elbow contractures and mild weakness of triceps, biceps, and scapular fixator muscles; occasionally as isolated cardiomyopathy

1:100,000 of all births  
 X-linked recessive form Xq28 and autosomal-dominant form 1q21.3

X-linked form involves gene for emerin and dominant form gene for lamin A/C. Emerin and lamin A/C are attached to nuclear membrane. Their functions are not yet known.

5–10× above normal

Normal nerve conductions; EMG often normal in early stages

Mild to moderate active myopathy with occasional atrophic type 1 fibers

Mutations in the *EDMD* gene encoding emerin and *FHL1* gene encoding FHL1 in X-linked EDMD; Mutations in *LMNA* gene encoding lamin A/C for AD-EDMD and AR-EDMD

**Figure 293-1** Boy who has Duchenne muscular dystrophy demonstrating the sequence of maneuvers that constitutes Gowers sign. The child pushes off the floor with all 4 extremities, then prepares to push up by moving the hands along the floor closer to the feet, and finally places the hands on the thighs and pushes up to the erect position. The maneuver is necessary because of the marked weakness of the hip extension. (From Swaiman KF. *Pediatric Neurology: Principles and Practice*. 2nd ed. St Louis, MO: CV Mosby; 1994. Copyright © 1994, Elsevier, with permission.)

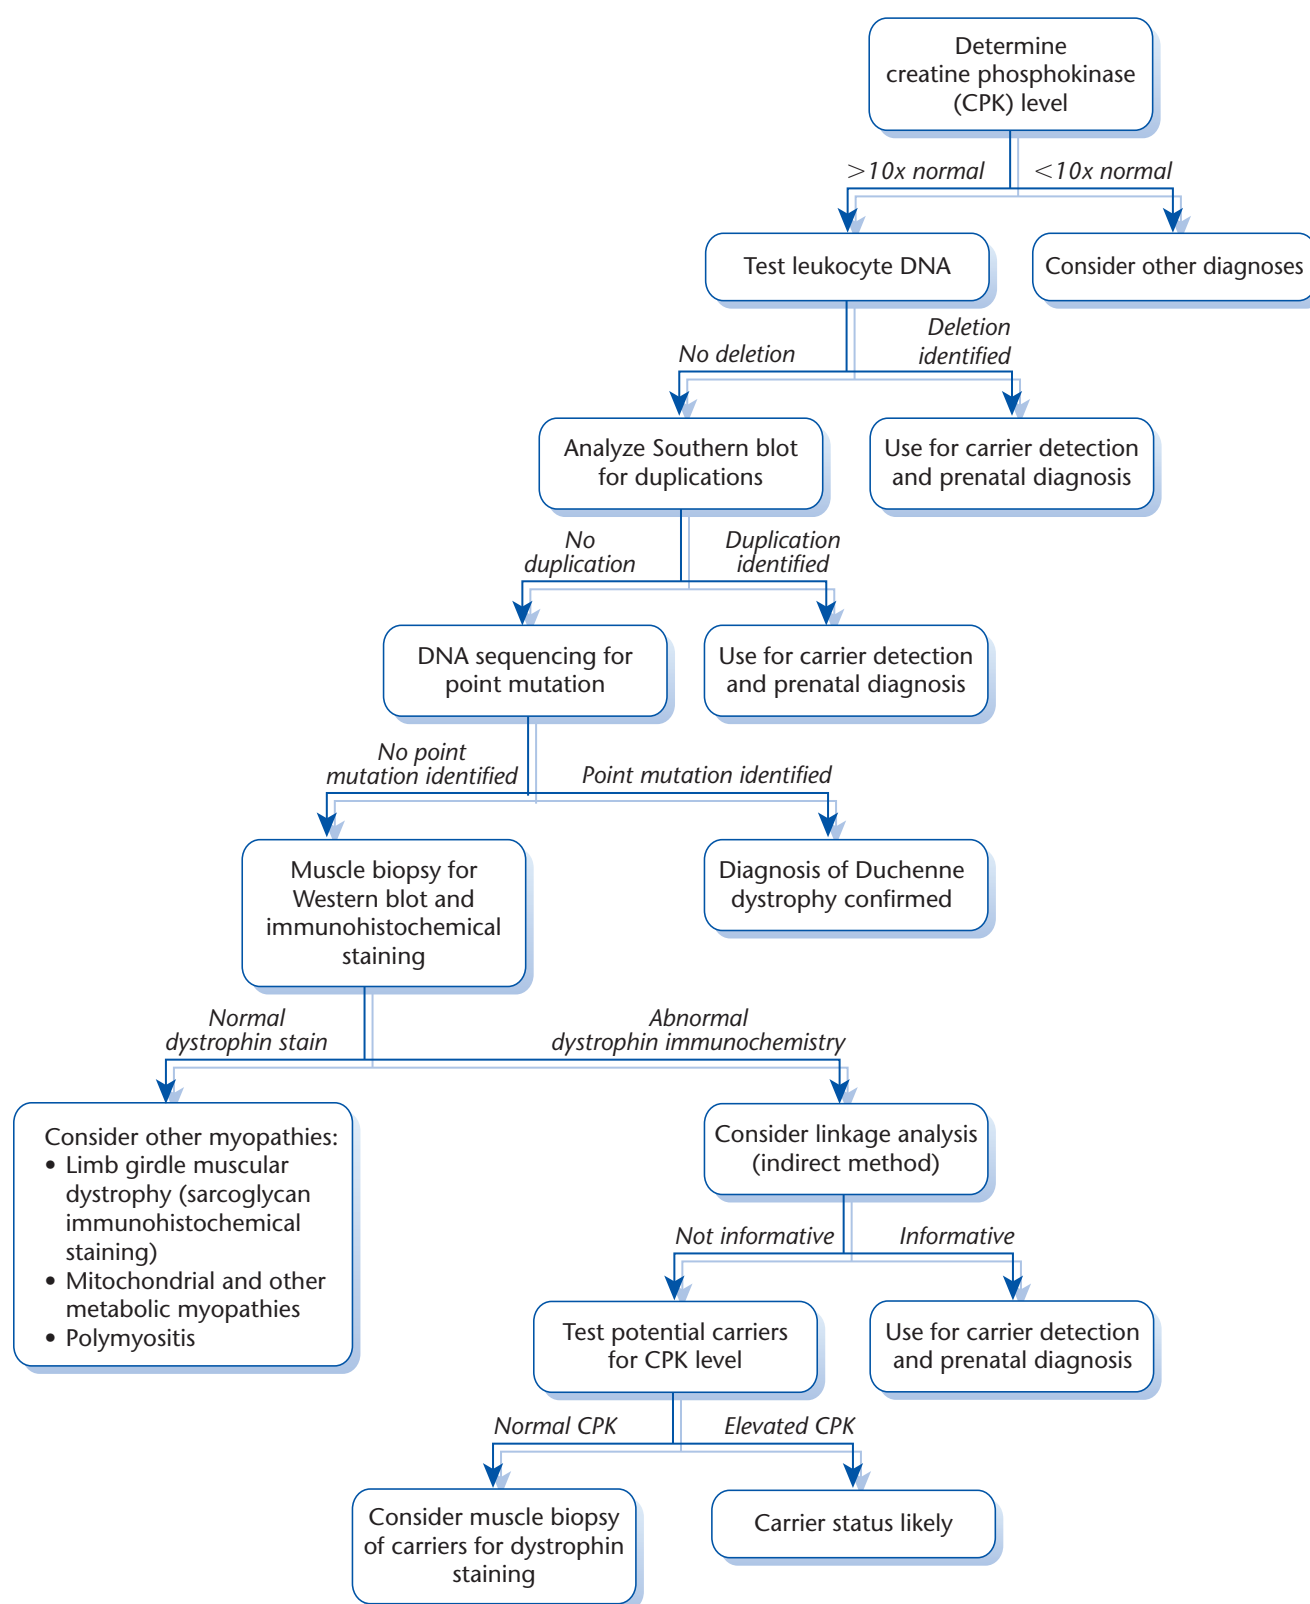

joint contractures (especially of the Achilles tendons), respiratory insufficiency, scoliosis, gastrointestinal hypomotility, and cardiomyopathy. Table 293-2 summarizes the principal problems and treatment options.

The patient and family need to work closely with physicians, schoolteachers, physical educators, and physical and occupational therapists to develop an individualized care plan for the child at each stage of the disease. Early in the illness, the child can usually play with peers in most activities; however, by the first or second grade, some adaptation of physical education requirements becomes necessary. The natural history of Duchenne dystrophy in the absence of treatment with corticosteroids predicts that the child will require a wheelchair for independent mobility between 10 and 12 years of age. Contractures and scoliosis both develop when the child is no longer able to ambulate; they do not appear at a specific age but depend on the child's functional status.

Physical therapy is often consulted at the time of diagnosis or 4 to 6 years of age. Therapy should emphasize range of motion and a home stretching program, particularly for the ankles. Strengthening programs should be avoided as possibly deleterious and the child's energy should be reserved for fun and functional activities. Aquatherapy is ideal if available. Since the use of corticosteroids became the standard

of care, the need for tendon release surgery and spinal stabilization surgery for scoliosis has decreased. Because the Achilles tendon contractures develop after patients can no longer ambulate, surgical lengthening and bracing usually do not affect functional status, and should be reserved for cases where the contractures limit normal positioning and transfers. Although historically tendon lengthening was common, surgical lengthening is now rarely done in ambulatory patients since toe walking is adaptive to maintain walking in the presence of severe proximal muscle weakness. In a Cochrane review of surgery versus controls, controls have better function at 12 months and surgical patients have contracture recurrence at 24 months. Steroids have no direct effect on contracture formation except secondary to maintaining proximal muscle strength. Orthopaedic consultation becomes a particular need in the early nonambulatory stage of Duchenne dystrophy to monitor for the development of scoliosis and tendon contractures that limit sitting ability, because this is when contractures and spinal curvature become prominent. The orthopaedic care, physical therapy, occupational therapy, and neurologic care are often coordinated by the neuromuscular specialist and are typically provided in a clinic financed partly by the Muscular Dystrophy Association (MDA). Scoliosis surgery requires complex

**Figure 293-2** Flowchart outlining diagnostic tests for a boy suspected of having Duchenne muscular dystrophy without a family history of this disorder.

**Table 293-2** Complications and Treatment of Muscular Dystrophies in Childhood

CHARACTERISTIC	DUCHENNE DYSTROPHY	BECKER DYSTROPHY	MYOTONIC DYSTROPHY
Muscle weakness	Treatment with prednisone or deflazacort slows deterioration or stabilizes muscle strength.	No controlled studies of prednisone treatment	No specific therapy; braces for foot drop; children can usually participate in physical education in school.
Respiratory problems	Forced vital capacity is monitored (in later stages, atelectatic pneumonitis is common); colds are treated aggressively; if signs of respiratory failure develop, nasal or oral ventilation should be considered.	Uncommon until late stages; management then as with Duchenne dystrophy	For congenital cases, ventilation is often needed; the prognosis for survival is poor if the patient is ventilator dependent at >4 weeks; other management is as for Duchenne dystrophy.
Cardiac problems	Cardiomyopathy often leads to congestive heart failure in the late stages of the disease; afterload-reducing therapy often helps; patient should be monitored for intracardiac clots.	Severe cardiomyopathy may require cardiac transplant; CHF treatment is the same as for Duchenne dystrophy	Occasionally, tachyarrhythmias or heart block develops in childhood forms, and pacemaker treatment is indicated.
Orthopaedic problems	Achilles tendon contractures respond to stretching in early stages; later, tendon release surgery is sometimes performed; contractures at the hips, knees, elbows, and wrists usually develop after the patient becomes wheelchair limited; scoliosis often develops when patients stop ambulating; spinal stabilization surgery is often unnecessary in patients receiving long-term corticosteroid treatment. Risk vs benefit depends on total medical picture and some patients may experience a slowing in rate of weakness in pulmonary function. The role of spinal stabilization surgery is currently being re-evaluated.	Uncommon; contractures are much less common than in Duchenne dystrophy	Talipes deformity requires treatment with stretching and orthotic support; occasionally, surgery is necessary.
Nervous system problems	Increased incidence of cognitive and behavioral problems; some patients improve with small doses of methylphenidate.	Uncommon	Intellectual disability is common, especially in congenital cases, and special classroom care is needed; hearing deficits are common and may require hearing aids; facial weakness, dysarthria, and hearing problems exaggerate the impression of intellectual disability.
Gastrointestinal problems	Constipation is common, especially late in the disease; careful dietary monitoring, stool softeners, and good water intake (urine specific gravities 1.007–1.010) are usually effective; occasionally, acute gastric dilation occurs; it resolves over 2–3 days with nasogastric tube decompression of the stomach and intravenous hydration.	Uncommon	Spastic colon-type complaints with abdominal pain are common; occasionally, these symptoms improve with antimyotonia therapy with mexiletine; eating small portions at each meal diminishes tendency to aspirate.

FACIOSCAPULOHUMERAL DYSTROPHY	CONGENITAL MUSCULAR DYSTROPHIES	EMERY-DREIFUSS MUSCULAR DYSTROPHY
<p>No specific treatment; patients should avoid lifting with arms fully extended and abducted; braces are sometimes needed.</p> <p>Uncommon</p>	<p>No specific treatment; bracing and physical therapy are useful in some patients.</p> <p>As with Duchenne dystrophy; patients often die of respiratory failure late in childhood or in early teens.</p>	<p>No specific treatment; skeletal muscle weakness is often relatively mild compared with cardiac problems and does not limit function.</p> <p>Mild other than symptoms related to cardiac dysfunction.</p>
<p>Uncommon</p>	<p>Uncommon</p>	<p>Frequent cardiac conduction defects; atrial paralysis, cardiac arrest, and sudden death are common; pacemaker treatment and preventive therapy for cardiac emboli are often necessary.</p>
<p>Occasionally, knee effusion and low back pain develop as a result of weakness; conservative care measures are effective; in late stages, surgery to stabilize the scapula may be performed, but surgery is uncommon.</p>	<p>Contractures develop in 70% of patients by 3 months of age at the ankles, knees, hips, and feet.</p>	<p>Contractures, especially in the elbows and ankles, occur early and respond somewhat to physical therapy; surgical release of Achilles tendon may be necessary; some patients develop a rigid spine syndrome, for which no effective therapy is available.</p>
<p>Uncommon; in rare cases, the infant-onset form of the disease occurs in association with hearing loss, retinal disease, or both.</p>	<p>Intellectual disability common; magnetic resonance imaging of head shows increased signal from white matter on T2-weighted images; occipital agyria; most patients have microcephaly, polymicrogyria, pachygyria, and heterotopias; generalized or focal seizures occur in most patients; anticonvulsant therapy is necessary.</p>	<p>Caused only by stroke from heart block or cardiac emboli.</p>

multidisciplinary decision making. There have been no randomized trials to help define risks versus benefits. Surgery may improve lung function, comfort, and longevity, or it may hasten loss of self-feeding skills and have overall negative effects on quality of life.

Spinal stabilization surgery has become much less common, related in large part to long-term corticosteroid therapy slowing or preventing significant progression of scoliosis during the teenage years. The timing and decision to perform spinal stabilization needs to be individualized to each patient and needs to be coordinated with consultants in orthopaedics, pulmonary medicine, and cardiology as well as with the child's primary care physician and neuromuscular specialist.

Although MDA clinics provide an excellent opportunity to offer multiple services to patients, the role of the primary care physician remains critical. The pediatrician usually provides routine care of upper respiratory infections and routine immunizations, as well as treatment for other common medical problems. In the middle and late nonambulatory stages of Duchenne dystrophy, minor medical problems can provoke major complications. A mild cold may lead to atelectatic pneumonitis and acute respiratory insufficiency. Such a problem, if treated aggressively, is fully reversible. Even chronic constipation can produce respiratory compromise in the later stages of Duchenne dystrophy, because of abdominal distention and upward pressure on the diaphragm. An effective regimen to maintain regular bowel movements becomes important in routine care. Respiratory insufficiency often develops in the late stages of Duchenne dystrophy. Forced vital capacity declines, usually into the range of 600 to 1,000 mL. Management options include nasal ventilation rather than positive pressure ventilation via tracheostomy. Monitoring pulmonary function and screening for nocturnal hypoventilation is essential for proactive use of respiratory aids. Coordination of care with pulmonary medicine consultants and serial monitoring of pulmonary function tests is essential. This monitoring of pulmonary status is necessary to determine the frequency of screening evaluations for nocturnal hypoventilation and initiation of noninvasive nighttime respiratory support with either continuous positive airway ventilation (CPAP) or biphasic positive airway ventilation (BiPAP). The patient is also at risk for obstructive sleep apnea, and a history of snoring should prompt screening for nocturnal hypoventilation even in the absence of significantly decreased pulmonary test results. Noninvasive ventilation requires either nasal, mouth or whole-face masks and close work with respiratory therapy and pulmonary medicine. Invasive tracheostomy and positive pressure ventilation have become uncommon as the noninvasive therapy has received greater use. The use of assistive cough devices (insufflator-exsufflator) is helpful in speeding recovery from episodes of bronchitis and pneumonia. Ventilatory care is usually coordinated among the pediatrician, neuromuscular specialist, pediatric pulmonologist, and patient and family. All have to participate if the treatment plan is

to be effective. Considerable discussion is necessary to educate the patient and family at this stage and to help decide which options are most appropriate. Physicians and nurses who have special training in neuromuscular diseases are often the ones who educate the family, and the roles of the pediatric pulmonologist and pediatrician have to be tailored to each medical care setting.

Periodic consultation with a pulmonologist is important once a child with Duchenne dystrophy is no longer ambulatory. Patients should be monitored for the development of obstructive sleep apnea and nocturnal hypoventilation with periodic polysomnograms. Pulmonary clinic visits typically include measurements of vital capacity, inspiratory and expiratory pressures, and cough peak flow, all of which guide prognosis and expectations regarding the need for ventilatory support and airway clearance assistance during respiratory infections. Pulmonary consultation before and after general anesthesia is an integral part of any elective surgery. This preoperative consultation needs to include training of the patient and the home care providers in the use of assisted coughing techniques and in the use of nasal bilevel positive airway pressure (BiPAP). The use of nasal BiPAP and assisted coughing hastens recovery after general anesthesia and decreases the likelihood of postoperative respiratory complications.

In the late stages of Duchenne dystrophy, patients often develop cardiomyopathy. A chest radiograph reveals a dilated heart, and the cardiac ejection fraction decreases to 10% to 20% of normal. Heart failure is often exacerbated by coexisting respiratory insufficiency. In all of these cases, simultaneous ventilatory support must be considered if the patient and family have decided to pursue a vigorous course of treatment. Heart failure is difficult to manage, and afterload reduction therapy is often more effective than digoxin. An initial trial with an angiotensin-converting enzyme inhibitor, such as lisinopril, is often undertaken. If left-ventricular function worsens, then treatment with beta-blocker therapy, such as carvedilol, is initiated with the goal of keeping the heart rate between 55 and 70 beats per minute. Cardiology consultation needs to guide the care plan. Occasionally, ventricular or atrial clots (or both) are present, and long-term anticoagulant therapy is necessary.

Acute gastric dilation is another infrequent complication in the late stages of Duchenne dystrophy. This condition typically occurs in association with an idiopathic metabolic acidosis and responds rapidly to nasogastric tube decompression of the stomach and intravenous hydration. Caution must be used with intravenous repletion of potassium, because in the late stages of the disease the patient's muscle mass is considerably diminished and is not available to buffer an acute rise in extracellular potassium.

Although the cause of the gastric dilation is unknown, this problem, as well as the chronic intestinal hypomotility (constipation), probably results from the deficiency of dystrophin in the smooth muscle of the gastrointestinal tract. Good hydration, a balanced

dietary intake, and regular bowel habits are the mainstays of treatment for these problems.

Comprehensive care guidelines have been published and provide a useful framework for all practitioners who care for individuals with Duchenne dystrophy.

### **Corticosteroid (Prednisone and Deflazacort) Treatment**

Corticosteroids (prednisone and deflazacort) are the only effective, evidence-based therapy for Duchenne dystrophy. Corticosteroid treatment is the standard of care, and studies indicate that daily prednisone or deflazacort is the most effective short- and long-term treatment to maintain muscle strength and function. The mechanism responsible for the beneficial effect of prednisone is unknown. However, several clues exist about the process involved. The increase in strength begins to develop after only 10 days of treatment and reaches a maximal response after 3 months of therapy. Muscle mass increases 10% after 3 months of prednisone treatment, and the rate of muscle breakdown declines in association with maintenance of a normal rate of muscle protein synthesis. Although azathioprine immunosuppressive therapy has been used, it confers no beneficial effect, which argues against the possibility that an immunosuppressive effect accounts for the improvement in muscle strength with the use of prednisone.

Treatment of Duchenne dystrophy patients with prednisone or deflazacort (not FDA approved in the United States but used in Canada and Europe) is now routine, but it is best carried out and monitored in medical centers experienced with its actions and side effects and with the clinical manifestations and complications of Duchenne dystrophy. Weight gain is an early side effect of corticosteroid therapy. Long-term benefits of corticosteroids are prolonged ambulation, prolonged stabilization of pulmonary function, reduced need for spinal stabilization surgery, and improved quality of life. The most common side effects are excessive weight gain, mood disturbances (more aggressive, more tearful), and cushingoid facial appearance. More serious side effects (compression fractures of the spine, delayed puberty, high blood pressure, gastrointestinal bleeding, severe infections, or diabetes) are uncommon. Some patients have developed small, dot-shaped cataracts; others, as expected, have experienced decreased linear growth, which has probably helped maintain ambulation. One recent multicenter study compared intermittent (10 days “on,” 10 days “off”) to daily prednisolone given for approximately 4 years. The median loss of ambulation was 12 years in intermittent and 14.5 years in daily treatment. Side effects were more apparent with daily treatment. Another prospective trial of treatment comparing prednisone 0.75 mg/kg/d to prednisone 0.75 mg/kg/d (10 days on and 10 days off) and to deflazacort 0.9 mg/kg/d for 30 to 60 months is in progress (see ClinicalTrials.gov, and search using the identifier NCT01603407).

To allow monitoring for the development of side effects, patients are seen every 3 to 6 months, depending

on their clinical picture, to assess weight, blood pressure, pulse, and forced vital capacity checks; for urinalysis; and for assessment of neuromuscular functioning. At each visit, the patient undergoes timed function tests (time needed to travel 30 feet, to arise from supine to standing position, and to climb 4 standard steps) and a muscle strength evaluation (shoulder abductors, elbow flexors and extensors, knee extensors, hip flexors and extensors). These measures help guide the physicians in adjusting the dose of prednisone. The blood count and serum electrolyte levels are measured at 6-month intervals.

With close follow-up, patients have been kept stable or showed only mild progression of muscle weakness for periods exceeding 5 years. Even in the late stages, prednisone seems to maintain respiratory muscle power and has reduced the number of patients who develop respiratory failure.

Current recommendations by the Guideline Development Subcommittee of the American Academy of Neurology concluded that in children with Duchenne muscular dystrophy, prednisone should be offered to improve strength and pulmonary function, improve timed motor function, reduce risk of need for scoliosis surgery and delay the onset of cardiomyopathy.

The discovery of the gene in Duchenne dystrophy and the ability to manufacture small segments of DNA containing the normal gene for dystrophin has raised hopes that direct gene therapy, either by local injection or by viral vector, will prove feasible. Research is in progress. Other advances in research include treatments to *read through* stop codon mutations or to skip certain exons in order to re-establish a reading frame and allow dystrophin transcription (exon skipping) stem cell therapy and treatments to *read through* certain types of mutations. Cost-effective newborn screening with CK is also being studied. This will help identify patients for novel therapeutic treatments prior to onset of clinical symptoms.

### **Other Muscular Dystrophies in Childhood**

Myotonic dystrophy type 1 (DM1), or dystrophica myotonia (Steinert disease), is caused by an abnormal enlargement of a trinucleotide repeat in the third non-translated region of the *DM* gene on chromosome 19. Discovery of the gene has led to the development of gene probes to identify both symptomatic and asymptomatic carriers. Genetic counseling and prenatal testing can now be performed with a high degree of accuracy, an important advance in preventive therapy. Myotonic dystrophy type 2 (DM2) is a disorder similar to but distinct from DM1 and is also a multisystem autosomal-dominant disorder associated with myotonia, weakness, and cataracts. However, DM2 does not occur in infancy or childhood. Complications can occur, particularly in DM1, when patients receive anesthetics and during pregnancy and delivery.

Facioscapulohumeral dystrophy (FSHD) sometimes has onset in childhood. Severe cases that uncommonly occur in infancy and early childhood may result in considerable weakness of facial and bulbar muscles, and affected patients can develop respiratory insufficiency along with generalized weakness. The disease

**Table 293-3** Autosomal-Dominant Forms of Limb Girdle Muscular Dystrophy (LGMD 1A-H)

DISEASE NAME	GENE	CHROMOSOME LOCUS	AGE OF ONSET	CREATINE KINASE	CLINICAL FEATURES	OTHER FEATURES
LGMD1A myotilinopathy	<i>MYOT</i> or <i>TTID</i>	5q31.2	18 and older	Normal to moderately high	Proximal weakness; distal weakness late; ankle contractures	Dysarthria; dysphagia; respiratory insufficiency
LGMD1B	<i>LMNA</i>	1q22	Birth to adulthood	Normal to high	Lower extremity weakness; late upper extremity weakness; contractures as in Emery-Dreifuss muscular dystrophy	Atrioventricular conduction defects; dilated cardiomyopathy
LGMD1C caveolinopathy	<i>CAV3</i>	3p25.3	Any	Moderately to very high	Mild to moderate proximal weakness; cramps after exercise; myalgias	Calf hypertrophy; muscle rippling; hypertrophic cardiomyopathy
LGMD1D desminopathy	<i>DES</i>	2q35	Early adulthood	Normal to moderately high	Mostly lower extremity weakness sparing quadriceps; ambulation preserved	Cardiac conduction defects; dilated cardiomyopathy
LGMD1E	<i>DNAJB6</i>	7q36.3	18–40; late onset in females	Normal to moderately high	Slowly progressive weakness in lower extremities sparing quadriceps	Calf hypertrophy; loss of ambulation 20–30 years from onset
LGMD1F	<i>TNP03</i>	7q32.1–q32.2	Any	Normal to high	Fast progression in early onset cases; facial weakness	Scoliosis; respiratory failure
LGMD1G	<i>HNRPDL</i>	4q21	Adulthood	Normal to very high	Proximal lower extremity weakness	Finger and toe flexion limitation
LGMD1H	?	3p25-p23	Second to fifth decade	Normal to very high	Slowly progressive upper and lower extremity weakness	Calf hypertrophy; muscle atrophy; high serum lactate

is inherited in an autosomal-dominant manner and is caused by a deletion in the number of D4Z4 repeats in the subtelomeric region of chromosome 4q35. DNA testing is available. FSHD type 1 represents approximately 95% of patients and results from a deletion of a key number of repetitive elements on chromosome 4q35. The remaining 5% of FSHD cases are classified as FSHD type 2 and result from a digenic mutation rather than a loss of D4Z4 repeat units. The clinical presentations of FSHD type 1 and FSHD type 2 are indistinguishable.

The infant-onset congenital muscular dystrophies are rare disorders and have already been mentioned in the discussion of the differential diagnosis of Duchenne dystrophy.

Emery-Dreifuss muscular dystrophy is a rare, hereditary disorder, having X-linked, autosomal recessive, and autosomal dominant that are clinically and genetically distinct from, but occasionally confused with, Becker

dystrophy. It can produce severe cardiac complications that require urgent treatment. These cardiac symptoms may prompt medical evaluation before the muscle weakness or contractures occur.

Table 293-3 and Table 293-4 outline the forms of autosomal-dominant and autosomal-recessive forms of LGMD. Some of these disorders can occur during childhood or adolescence and on superficial evaluation, they resemble Duchenne dystrophy. Unlike Duchenne dystrophy, most of the forms of LGMD progress more slowly, and the prognosis differs. The autosomal-dominant forms (LGMD 1A-H) are especially uncommon, as are some of the autosomal-recessive forms (LGMD 2A-V). However, the sarcoglycanopathies (especially LGMD 2I) probably account for more than 10% of patients who have a limb-girdle pattern of muscle weakness and whose muscle biopsy samples stain normally for dystrophin. The sarcoglycans are glycoproteins associated with

dystrophin and other muscle membrane-associated proteins with relationships to specific forms of LGMD, and these different disorders have different causes.

The various forms of LGMD are important to consider in referring children to a neurologist. Simply being aware that a variety of uncommon muscular dystrophies with different prognoses exists will help parents and patients understand that different tests may be necessary to establish a specific diagnosis, a prognosis, and a plan of treatment.

### WHEN TO REFER

Neuromuscular clinic or specialist

- When the diagnosis of Duchenne dystrophy is strongly suspected (ie, symptoms and high creatine kinase levels)
- To facilitate the workup
- Once the diagnosis is confirmed to establish multidisciplinary care

Genetic counselor

- After the diagnosis of Duchenne dystrophy is established
- Offered to family members of patients, especially at-risk carrier women

Cardiologist

- At diagnosis to obtain a baseline cardiologic evaluation
- If any wall motion abnormality is present on echocardiogram, delayed enhancement on cardiac MRI, or suspicion of arrhythmia
- In the late stages of the disease for monitoring of cardiac function and management of cardiomyopathy and heart failure
- Before surgery

Pulmonologist

- To obtain a baseline pulmonary evaluation at time of diagnosis
- In the late nonambulatory stage of the disease to monitor forced vital capacity (FVC), cough pick flow, maximum inspiratory pressure (MIP), and maximum expiratory pressure (MEP) and manage respiratory failure with noninvasive ventilatory support; to discuss tracheostomy
- Before surgery to maximize use of cough assist and BiPAP as necessary

Orthopaedic surgeon

- To obtain a baseline orthopaedic consultation at time of diagnosis
- After the patient with Duchenne dystrophy has lost ability to walk
- For consideration of scoliosis surgery or release of heel cord contractures when the nonambulatory patient shows signs of spinal curvature or progressive heel cord contractures

Physical therapist, occupational therapist, or both

- During the ambulatory stage of Duchenne dystrophy, to develop a heel cord stretching program and an individualized exercise program
- In the late ambulatory stage of Duchenne dystrophy, when the patient may seem to be close to becoming wheelchair limited

- To be fitted with adaptive equipment and night braces
- To evaluate and manage contractures

Dietitian

- During the ambulatory stage of Duchenne dystrophy, particularly in patients receiving corticosteroid treatment
- To help manage weight gain
- To establish a healthy eating pattern for the future

Neuropsychologist

- During the ambulatory and nonambulatory stages of Duchenne dystrophy because these patients are at risk of having emotional, cognitive, and behavioral problems
- In patients with borderline intellectual abilities
- In patients with cognitive or behavioral abnormalities
- In patients and family members who need end-of-life counseling

### WHEN TO ADMIT

- After surgery for 24 hours (or longer, depending on the type of surgery) to monitor cardiac and pulmonary function
- For evaluation and management of pneumonia or respiratory insufficiency, especially in nonambulatory patients with Duchenne dystrophy and in patients with advanced cardiomyopathy with cardiac failure

## Chapter 294

### NEPHRITIS

William S. Varade, MD

#### DEFINITION

Nephritis is the general term for noninfectious inflammation of the kidney parenchyma. This inflammation may involve primarily the glomerulus (glomerulonephritis), the tubules and interstitium (tubulointerstitial nephritis), or both. Because glomerulonephritis historically has been the subject of more intense interest, when the term *nephritis* is used, many physicians think only of glomerular lesions.

#### CLINICAL MANIFESTATION

The components of a classic nephritic syndrome are hematuria, proteinuria, the presence of red blood cell casts in the urine, oliguria, hypertension, and uremia. Some or all of these parameters may be evident initially. The finding of hematuria and proteinuria together strongly suggests underlying glomerular inflammation. Hematuria may be microscopic or macroscopic. Proteinuria can range from mild to nephrotic range. Presentation can range from acute, with sudden onset of gross hematuria, edema, and oliguria, to subacute or chronic, with a more protracted course in which symptoms may be lacking and urine abnormalities detected on routine urinalysis are the only findings.

#### INCIDENCE

The true incidence of nephritis in children is difficult to ascertain. Many cases of acute glomerulonephritis may be mild and self-limited and thus go undetected or not lead to biopsy. In a study of 487 children younger than 15 years who underwent renal biopsy, 43% had a diagnosis of glomerulonephritis. Only 8.4% of these had a classic nephritic picture with hematuria, hypertension, oliguria, edema, and reduced glomerular filtration rate. Thus, incomplete nephritic syndrome presentations are more common in children who are ultimately diagnosed with nephritis. Incidence reports of nephritis may be skewed by differing criteria for biopsy in different parts of the world and by differences in the frequency of specific nephritides in different regions.

#### GENERAL EVALUATION OF SUSPECTED NEPHRITIS

Blood pressure should be monitored carefully and frequently in any patient with suspected nephritis, and it should be compared with normal values for gender, age, and height percentiles. Weight should be measured. Significant weight gain compared with values from prior visits might suggest fluid retention. Similarly, poor growth with crossing height percentiles

#### BOX 294-1 Glomerulonephritides With Low Complement Levels

- Acute poststreptococcal glomerulonephritis
- Lupus nephritis
- Membranoproliferative glomerulonephritis
- Nephritis of chronic infection
- Cryoglobulinemia

and inappropriate weight gain or loss might suggest a chronic renal disorder. Children with nephritis may have the following findings on physical examination: periorbital or pretibial edema, changes in eye grounds, a uremic odor to the breath, pleural or pericardial friction rubs, ascites, costovertebral angle tenderness, joint swelling or tenderness, and vasculitic rashes.

Laboratory evaluation should include urinalysis with microscopy, serum electrolytes, blood urea nitrogen, creatinine, calcium, phosphorus, albumin, liver enzymes, and complete blood count with platelets. Decreased levels of the third component of complement (C3) and on occasion that of the fourth component (C4) can help narrow the differential diagnosis by distinguishing the hypocomplementemic nephritides from those with normal complement levels (Box 294-1). Antinuclear antibody and antistreptolysin O or other antibodies to streptococcal antigens should be obtained. Anti-double-stranded DNA (anti-dsDNA), antineutrophil cytoplasmic antibodies, and hepatitis B and C serologic tests may be useful in cases of lupus nephritis, Wegener granulomatosis, and microscopic polyangiitis, and in some cases of membranoproliferative glomerulonephritis or membranous nephropathy. Although pyelonephritis can usually be distinguished from glomerulonephritis on clinical grounds, urine culture should be obtained in unclear cases. Imaging studies, in general, are nonspecific and not helpful in evaluating patients with nephritis.

#### ACUTE GLOMERULONEPHRITIS

Acute glomerulonephritis is characterized by the abrupt onset of hematuria, proteinuria, hypertension, and edema. The hematuria is often grossly visible as tea- or cola-colored urine. In some children, however, the hematuria may be microscopic only. Red blood cell casts and dysmorphic red blood cells are present, although several urine samples may have to be examined to demonstrate them (Figure 294-1). White blood cells on microscopy and a positive test for leukocyte esterase are often found but suggest inflammation and not bacterial infection. Acute glomerulonephritis is often the initial presentation of the renal diseases listed in Box 294-2.

This clinical syndrome can have 2 presentations: acute glomerulonephritis with no or mild renal failure and acute glomerulonephritis with rapidly progressive renal failure.

**Figure 294-1** Red blood cell cast (unstained).

**BOX 294-2 Acute Glomerulonephritides That Are Usually Characterized By No or Mild Renal Failure**

**MORE COMMON**

- Acute poststreptococcal glomerulonephritis
- Henoch-Schönlein purpura with nephritis
- Postinfectious (nonstreptococcal) glomerulonephritis
- Interstitial glomerulonephritis
- Radiation nephritis

**LESS COMMON**

- Acute episodes in patients with chronic glomerulonephritis
- Hemolytic-uremic syndrome (milder cases)
- Membranoproliferative glomerulonephritis (some)
- Nephritis of systemic lupus erythematosus (some)

## ACUTE GLOMERULONEPHRITIS WITH NO OR MILD RENAL FAILURE

### Acute Poststreptococcal Glomerulonephritis

Acute poststreptococcal glomerulonephritis (APSGN) is a common form of glomerulonephritis in childhood. The true incidence is unknown because many cases are subclinical. The greatest burden of disease occurs among poor populations in less developed countries. The peak incidence has historically occurred at age 7 years, and it is less common before age 3 years. However, more recently, at least in the developed world, elderly people seem to be more frequently affected.

There is a slight predominance among boys. Sporadic cases of APSGN are most common, although epidemics may occur. Cases of nephritis after streptococcal pharyngotonsillitis are more common in temperate regions, whereas those after streptococcal skin infections are more common in tropical and subtropical climates.

### Etiology

Poststreptococcal glomerulonephritis is the consequence of the host immune response to a nonrenal infection with group A  $\beta$ -hemolytic streptococci (GABHS), although cases associated with group C and G streptococcal infection have been reported as well. Not all GABHS strains are nephritogenic. Nephritogenic strains include types 1, 2, 4, 12, 18, 25, 49, 55, 57, and 60 and possibly some nontypable strains. Types 12 and 49 are the strains most commonly associated with nephritis. The pathogenesis of APSGN remains uncertain. One possibility is that streptococcal proteins are released and lodge in the glomerulus, where they form nephritogenic immune complexes leading to complement activation. Prominent among the candidates for the suspected streptococcal nephritogenic antigen are the nephritis-associated plasmin receptor (NAPlr) and streptococcal pyrogenic exotoxin B (SPEB). These proteins induce an antibody response, can be found in the glomeruli of patients with APSGN, and can activate complement, a form of immune complex-mediated disease. Approximately 15% of patients infected with a nephritogenic strain of streptococci subsequently develop nephritis. The risk for developing nephritis may differ according to site of infection (skin vs throat) and the particular M-type.

### Pathologic Features

The typical glomerular findings are proliferation of mesangial and endothelial cells, as well as the influx of polymorphonuclear leukocytes and mononuclear cells. The glomeruli are larger than normal, and the capillary lumens are compromised by the cellular proliferation within the glomeruli. By immunofluorescence microscopy, granular deposits of immunoglobulin and complement can be seen, corresponding to the subepithelial electron-dense humps seen on electron microscopy. With healing, the increased cellularity and immune deposits become limited to the mesangial region and then gradually resolve.

### Clinical Presentation

Mild and subclinical cases of APSGN are common. Renal involvement characteristically occurs 1 to 4 weeks after an infection caused by the nephritogenic streptococci, with a slightly longer lag time after a pyoderma. Most patients with APSGN exhibit macroscopic hematuria. Patients usually have oliguria and, in rare cases, anuria. Fluid retention leads to edema that is usually periorbital and, rarely, severe. Intravascular overload caused by salt and water retention can lead to signs of congestive heart failure. Approximately 60% to 70% of the patients have hypertension also related to salt and water retention. Patients who have severe hypertension may have symptoms of headache, drowsiness, vomiting, personality and visual changes, and convulsions. Anorexia and pain in the abdomen

or flank are common, although palpation of the abdomen usually does not reveal significant findings. Costovertebral angle tenderness often is present. Although a history of preceding skin or pharyngeal infection supports the diagnosis, such a history cannot be elicited in many cases.

### Laboratory Findings

The urine of children with APSGN usually is tea colored and opaque. The specific gravity is generally increased, and hemoglobin can be detected by dipstick testing. Proteinuria usually parallels the degree of hematuria and rarely reaches the nephrotic range ( $>40$  mg/m<sup>2</sup>/hour or  $>3.5$  g/day in older children and adults). Microscopic examination usually reveals red and white blood cells and granular or cellular casts. Because identifiable erythrocyte casts and dysmorphic erythrocytes may or may not be present, serial urine specimens may need to be examined.

Serum complement levels show a reduction of C3 in 80% of patients with APSGN and, very early in the course, a reduction of C4 in 50%. The erythrocyte sedimentation rate (ESR) is usually elevated. With severe oliguria, azotemia and acidosis may be seen. The plasma volume is usually expanded, causing a decline in serum protein, hemoglobin, and hematocrit levels by dilution. Hemolysis, a shortened erythrocyte half-life, and reduced erythrocyte production may contribute to these hematologic changes. Salt retention with a decreased fractional excretion of sodium is often seen even in the setting of increased intravascular volume.

Evidence of a preceding streptococcal infection can be important to support the diagnosis. The antistreptolysin O titer is elevated in 80% of patients, but increases in titer are less common in patients who have skin infection and in those who receive early treatment with antibiotics. When other streptococcal antibodies (antihyaluronidase, anti-deoxyribonuclease B) are measured, 80% to 90% of patients will have serologic evidence of preceding streptococcal infection. Cultures often are negative for GABHS by the time nephritis develops, particularly if antibiotics were prescribed.

The chest radiograph in patients who have significant fluid retention and hypertension may reveal a large heart with prominent pulmonary vasculature, pulmonary edema, or, in rare cases, pleural effusions. Ultrasound examination is nonspecific, usually revealing bilaterally enlarged echogenic kidneys.

### Course

The acute phase of APSGN will usually resolve after 1 week, heralded by diuresis. Creatinine levels should normalize by 3 to 4 weeks. Gross hematuria resolves within 1 to 3 weeks, although microscopic hematuria may persist for more than 1 year. Proteinuria generally resolves by 3 months but can last more than 1 year. Complement levels should normalize by 8 weeks. The presence of nephrotic-range proteinuria or extensive crescents by biopsy portends a poor prognosis. The failure of complement levels to normalize by 6 to 8 weeks suggests the presence of a form of nephritis other than APSGN, such as membranoproliferative

glomerulonephritis, the nephritis of chronic infection, or lupus nephritis.

### Treatment

Except for rapidly progressive glomerulonephritis (RPGN), which is discussed later, acute poststreptococcal glomerulonephritis most often resolves spontaneously and is not affected by corticosteroids or immunosuppressive agents. Even so, the pediatrician must be aggressive in treating hypertension, electrolyte derangements, uremia, oliguria, and the resulting vascular overload, pulmonary edema, and encephalopathy that may occur in the acute phase of the illness because these can be associated with significant morbidity and mortality.

Although mild hypertension may resolve spontaneously, more severe degrees of hypertension should be controlled with antihypertensive agents that act quickly. Because increased intravascular volume is theorized to be the main determinant of hypertension in acute glomerulonephritis, diuretics are a mainstay of therapy. Control of severe hypertension will often require the use of intravenous sodium nitroprusside, labetalol, nicardipine, or fenoldopam. Oral minoxidil may be effective. Slower acting, less potent antihypertensive drugs are not good initial choices but can be substituted after blood pressure has been acutely stabilized.

Oliguria results from decreased glomerular filtration and salt and water retention. In the absence of evidence of dehydration, administration of fluid boluses will not hasten the resolution of oliguria, and excessive fluid administration will worsen hypertension and fluid overload. The signs of congestive heart failure usually resolve with control of hypertension. Occasionally a patient develops acute kidney injury (AKI) severe enough to require dialysis.

A 10-day course of antibiotics is usually given to eradicate any remaining GABHS and thus prevent the spread of the organism to others. Treatment does not seem to affect the course of nephritis in the patient. Close contacts should be screened for streptococcal infection and treated if present.

Hospitalization for patients who have this disease needs to be determined individually (see When to Admit). Although many children who have mild episodes do well as outpatients, the sudden development of hypertension and oliguria may produce life-threatening symptoms quite rapidly, necessitating hospitalization. After the acute phase the child may be allowed to resume normal activities gradually. Every child should be monitored regularly until the hypertension, electrolyte and creatinine abnormalities, and serum complement values return to normal. To be certain of the diagnosis, a renal biopsy may be indicated for a child whose clinical or laboratory findings are atypical. Any child whose C3 value does not return to normal within 12 weeks should be considered for kidney biopsy.

### Prognosis

Studies have shown that more than 95% of children who have APSGN recover from their illness. Occasionally, patients who have severe involvement, as evidenced by nephrotic-range proteinuria or the presence

of extensive glomerular crescents on biopsy, may have residual damage or even progress to end-stage renal failure. About 7% of children with APSGN have persistent proteinuria, 5% hematuria, 3% hypertension, and 0.9% azotemia. Adults with APSGN tend to fare worse. For most children the critical period is early in the illness when potentially fatal hypertension or fluid overload presents a danger. In general, however, the kidneys have an outstanding recovery potential in this disease. Recurrences of APSGN are rare.

### Postinfectious (Nonstreptococcal) Glomerulonephritis

A variety of bacteria other than streptococci, including fungi, viruses, and parasites, have been associated with acute glomerulonephritis that is not caused by active renal infection. In children, significant renal involvement is unusual in infections caused by common viruses, and those who do have such involvement have no serologic evidence of recent streptococcal infection. In most cases the acute nephritis resolves spontaneously and gradually, and renal function returns completely. However, some infectious agents such as *Staphylococcus aureus*, *Mycoplasma* species, and Gram-negative bacilli can be associated with crescent formation and rapid deterioration of renal function. Treatment of the underlying infection often leads to remission of the nephritis in those with milder renal involvement.

### Henoch-Schönlein Purpura Nephritis

Henoch-Schönlein purpura (HSP) is a small-vessel vasculitis most often affecting children, with a peak incidence between 4 and 6 years of age. It is characterized by palpable purpuric lesions, arthritis, abdominal pain and gastrointestinal bleeding, and nephritis. Not all manifestations need be present at the same time. Renal involvement is the most significant complication of HSP. Its presentation can vary considerably from minimal abnormalities on urinalysis to an aggressive, rapidly progressive glomerulonephritis with nephrotic syndrome and renal failure. The true incidence of renal involvement in HSP is difficult to ascertain and has been reported to range from 20% to 90%, depending on the definition of renal involvement used and whether the report is from a referral center or not. (See Chapter 264, Henoch-Schönlein Purpura.) Most children with HSP have mild renal involvement and experience recovery within 3 to 6 months.

### Rapidly Progressive Glomerulonephritis

RPGN is a variant of acute glomerulonephritis characterized by symptoms of acute nephritis associated with relentless progression to renal failure over weeks or months. Although acute interstitial nephritis stemming from pyelonephritis or hypersensitivity to certain drugs may develop in this way, most cases are the result of glomerular disease. Almost any of the acute or chronic glomerulonephritides may at times exhibit a rapidly progressive course. This group includes rare cases of poststreptococcal glomerulonephritis, indicating the need to monitor renal function and the general clinical course closely

### BOX 294-3 Classification of Acute Glomerulonephritis With Rapidly Progressive Renal Failure

#### IMMUNE COMPLEX

- Postinfectious reaction
  - Streptococcal infection
  - Visceral abscess
  - Other
- Collagen-vascular disease
  - Systemic lupus erythematosus
  - Henoch-Schönlein purpura
  - Mixed cryoglobulinemia
- Primary renal disease
  - IgA nephropathy
  - Membranoproliferative glomerulonephritis
  - Unknown cases (ie, idiopathic)

#### NO IMMUNE DEPOSIT

- Unknown cause
- Vasculitis
  - Microscopic polyangiitis
  - Wegener granulomatosis
  - Hypersensitivity vasculitides
- Hemolytic-uremic syndrome

#### ANTI-GLOMERULAR BASEMENT MEMBRANE ANTIBODY

- With lung hemorrhage (Goodpasture syndrome)
- Without lung hemorrhage
- Complicating membranous nephropathy

Modified from Couser WG. Rapidly progressive glomerulonephritis: classification, pathogenetic mechanisms, and therapy. *Am J Kidney Dis.* 1988;11(6):449-464. Copyright © 1988, Elsevier, with permission.

even in seemingly routine cases. As shown in Box 294-3, RPGN can be classified into 3 categories based on immunopathologic findings as seen in kidney biopsies.

Systemic lupus erythematosus (SLE) not infrequently may result in an acute glomerulonephritis with a rapidly deteriorating course. Of the primary renal disease group, immunoglobulin A (IgA) nephropathy and membranoproliferative glomerulonephritis may result in this presentation as well.

Occasionally, patients who have undiscovered chronic renal failure suffer a sudden deterioration that may be interpreted as acute glomerulonephritis (Box 294-3). Evaluation of these patients often reveals evidence of pre-existing chronic renal failure, such as osteodystrophy or hyperphosphatemia.

Idiopathic RPGN without immune deposits is much less common among children. Etiologies of pauci-immune RPGN include granulomatosis with polyangiitis (formerly Wegener granulomatosis) associated with upper and lower respiratory findings, Churg-Strauss syndrome associated with extravascular granulomas,

hypereosinophilia, asthma and atopic allergies, and microscopic polyangiitis. The presence of antineutrophil cytoplasmic antibodies (ANCAs) in the serum may help distinguish these disorders from each other and from other causes of rapid deterioration of renal function. In particular, antimyeloperoxidase with a perinuclear or P-ANCA pattern of antibody staining is often associated with microscopic polyangiitis, whereas antiproteinase 3 with a cytoplasmic or C-ANCA pattern of antibody staining is often associated with granulomatosis with polyangiitis. Of note, some patients with pauci-immune RPGN test negative for ANCA. Anti-glomerular basement membrane (anti-GBM) antibody-mediated RPGN is even more rare in children.

The hemolytic uremic syndrome (HUS; see Chapter 263, Hemolytic-Uremic Syndrome) is a triad of AKI, hemolytic anemia, and thrombocytopenia, which in children is most frequently related to infection by shigatoxin-producing *Escherichia coli* O157:H7. It is the most common cause of community-acquired AKI in pediatric patients. This entity frequently follows a prodrome of hemorrhagic colitis. Nondiarrheal forms of HUS, including inherited forms leading to abnormal complement regulatory proteins, thrombotic thrombocytopenic purpura, and disseminated intravascular coagulation, are less common but have a poorer prognosis and must be included in the differential diagnosis.

Although the characteristic clinical and laboratory features of a particular RPGN presentation may suggest specific causative factors, a renal biopsy is indicated to make the diagnosis and to determine the extent of the disease.

Treatment of RPGN depends on the particular diagnosis, often determined by kidney biopsy. Methylprednisolone pulses are frequently given initially for fulminant cases of SLE nephritis, membranoproliferative glomerulonephritis, IgA nephropathy, HSP nephritis, granulomatosis with polyangiitis, and polyarteritis nodosa. These pulses are frequently followed by oral or intravenous cyclophosphamide, azathioprine, or methotrexate. Plasmapheresis may be helpful in anti-GBM antibody disease, atypical forms of HUS, thrombotic-thrombocytopenic purpura, and some other resistant forms of RPGN. Typical diarrhea-associated HUS is treated supportively.

## CHRONIC GLOMERULONEPHRITIS

The glomerulonephritides that follow a prolonged, chronic course may be associated with an acute or subacute nephritis or, more insidiously, with only an abnormal urinalysis in an asymptomatic patient. Advanced cases may be discovered during investigation of nonspecific complaints such as anorexia, intermittent vomiting, and malaise that are found to result from undiagnosed chronic renal failure. IgA nephropathy, Alport syndrome, the nephritis of SLE, and membranoproliferative glomerulonephritis commonly follow a chronic course. Non-nephritic causes of chronic kidney failure, such as renal dysplasia and obstructive uropathies with significant unrecognized parenchymal damage, should be considered in the differential diagnosis.

## IgA Nephropathy

IgA nephropathy was first described by Berger and Hinglais in 1969 and has also been called IgA-IgG nephropathy, or Berger disease.

### Etiology

The cause of IgA nephropathy is unknown. Abnormal glycosylation of the hinge region of the IgA antibody molecule has been observed and has been suggested as a possible mechanism of disease. Mesangial IgA deposition and complement activation may play a role in damaging the kidneys. Secondary forms of IgA nephropathy can be seen with inflammatory bowel disease and liver disease.

### Pathologic Features

The sine qua non for the diagnosis of IgA nephropathy is the finding of dominant or codominant IgA staining of the glomerular mesangium by immunofluorescence microscopy. IgG and C3 generally are seen as well. Histologically, a wide variety of glomerular lesions can be seen from essentially normal glomeruli to mesangial hypercellularity with an increase in mesangial matrix or focal segmental proliferative, necrotizing, or sclerosing lesions. IgA nephropathy is difficult to differentiate morphologically from HSP, which has led to speculation that HSP is a form of IgA nephropathy with systemic findings.

### Clinical Presentation

IgA nephropathy typically occurs in the second or third decade of life but can affect all ages. Males are affected more often than females and it seems to occur less frequently in blacks than in whites. Characteristically, children with IgA nephropathy have a sudden onset of painless gross hematuria concomitant with an infection, usually of the respiratory tract, which may be associated with flank pain, although presentation with microscopic hematuria with or without proteinuria seems to be more common in Asia. The gross hematuria usually clears within a few days to a week as the infection resolves. Frequently, gross hematuria recurs with subsequent infections. Microscopic hematuria may persist with or without proteinuria between episodes, or the urine may clear totally. The simultaneous onset of an upper respiratory tract infection with the gross hematuria helps differentiate this disease from APSGN, in which a delay between infection and hematuria is the rule. The absence of a rash, abdominal pain, and arthritis helps differentiate IgA nephropathy from the nephritis of HSP. Approximately 10% of patients with IgA nephropathy may have nephrotic syndrome or AKI at presentation.

### Laboratory Findings

Other than an abnormal urinalysis, laboratory studies at initial presentation and early in the disease, at least in milder cases, are often normal. In particular, hypocomplementemia and serologic evidence of recent streptococcal infection usually are absent. Azotemia, heavy proteinuria, and hypertension, when they do occur, are poor prognostic signs. A renal biopsy may be indicated in patients with renal

insufficiency, nephrotic-range proteinuria, or persistent hematuria and proteinuria to confirm the diagnosis. Evidence of glomerulosclerosis, crescents, or tubulointerstitial fibrosis on biopsy portends a poor prognosis.

### Treatment

Treatment of IgA nephropathy remains controversial. Suggested regimens for patients with poor prognostic indicators include angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and long-term, alternate-day prednisone, with or without methylprednisolone pulses. Control of hypertension, as for other renal diseases, is essential.

### Prognosis

Although IgA nephropathy was originally considered to be a benign disorder in children, 10% to 30% of pediatric patients are anticipated to progress to renal failure over the course of several decades. Progression has been related to higher amounts of proteinuria, the presence of hypertension, renal insufficiency at presentation, and the severity of the histologic changes found on the kidney biopsy.

### Thin Basement Membrane Nephropathy

Although not a chronic glomerulonephritis per se, thin basement membrane nephropathy (TBMN; benign familial hematuria) is characterized by persistent hematuria among similarly affected, otherwise healthy family members. As such, it is an important disorder in the differential diagnoses of both IgA nephropathy and Alport syndrome (see previous and following sections) and hypercalciuria. TBMN is a benign condition inherited as a dominant trait. Undoubtedly, many of the early reports included patients who had IgA nephropathy because of the similarities of clinical presentation and because renal biopsy specimens often were not obtained. This condition has also been called *benign recurrent hematuria*.

### Etiology

Mutations in the type IV collagen  $\alpha$ -3 and  $\alpha$ -4 genes have been associated with 40% of TBMN cases. It is unclear whether certain mutations of the type IV collagen  $\alpha$ -5 gene, the cause of most cases of Alport syndrome (discussed in detail later in this chapter), may also give rise to some TBMN cases. The cause of benign familial hematuria thus seems to be heterogeneous.

### Pathologic Features

Light and fluorescence microscopy of renal biopsy specimens are generally normal. Widespread thinning of the GBM is visible by electron microscopy. These pathologic findings may be similar to those seen early in the course of X-linked Alport syndrome in some women. Only the family history lacking progressive renal impairment, deafness, and eye findings distinguishes TBMN from early Alport syndrome.

### Clinical Presentation

Persistent asymptomatic microscopic hematuria in the absence of hearing loss, eye findings, proteinuria, or

progressive renal impairment is the usual presentation. Proteinuria is generally absent, especially in children, but may be present in some adults. Macroscopic hematuria may occur in up to 22% of patients.

### Laboratory Findings

All laboratory test results are usually normal except for the urinalysis, which shows dysmorphic-appearing red blood cells. Demonstrating the presence of hematuria in otherwise asymptomatic family members suggests this diagnosis.

### Course

Most cases are discovered by finding microscopic hematuria on urinalysis during a routine evaluation. The presentation of TBMN may be similar to IgA nephropathy. It was found to be the cause of isolated asymptomatic microscopic hematuria in approximately one-third of adults, whereas IgA nephropathy was responsible for another third of the cases. The hematuria is persistent, but renal failure, deafness, and eye findings do not develop, in contrast to Alport syndrome. No treatment is indicated for TBMN, and the prognosis is generally excellent.

### Alport Syndrome

Alport syndrome, or hereditary nephritis, is an inherited renal disease associated with sensorineural deafness and ocular abnormalities. Alport syndrome is inherited as an X-linked-dominant trait in 80% to 85% of cases. Families with Alport syndrome with autosomal-recessive inheritance (15% of cases) or, very rarely, autosomal-dominant inheritance have also been described. The combination of Alport features and macrothrombocytopenia is known as *Epstein syndrome*. Rarely, X-linked Alport syndrome can also be associated with leiomyomatosis.

### Etiology

X-linked Alport syndrome is caused by a mutation of the gene encoding the  $\alpha$ -5 chain of type IV collagen. Mutations range from point mutations, leading to an amino acid substitution or a premature stop codon, to small or large deletions. The particular type of mutation may influence the severity of the clinical expression of the disease. About 10% to 15% of cases represent new mutations. X-linked Alport syndrome with leiomyomatosis seems to arise from deletions involving the contiguous genes encoding the  $\alpha$ -5 and  $\alpha$ -6 chains of type IV collagen. Autosomal-recessive Alport syndrome has been related to mutations in the genes encoding the  $\alpha$ -3 and  $\alpha$ -4 chains of type IV collagen on chromosome 2. Autosomal-dominant Alport syndrome also has been linked to the region of chromosome 2 containing the genes encoding the  $\alpha$ -3 and  $\alpha$ -4 chains of type IV collagen.

### Pathologic Features

The characteristic findings of Alport syndrome are seen by electron microscopy of renal biopsy specimen. These findings include variations in the thickness of the GBM, with splitting and lamellation of the lamina densa of the GBM, giving it a basket-weave appearance. However, early in the course of the disease the

only ultrastructural abnormality may be diffuse attenuation of the GBM. Thus, in these cases, distinguishing patients with Alport syndrome from those with TBMN may be difficult based on biopsy findings alone. In these indeterminate cases, special stains for the individual type IV collagen chains may prove of value for making the correct diagnosis.

### **Clinical Presentation**

Renal disease is severe and progressive in male patients with X-linked Alport syndrome, with approximately 90% developing end-stage renal failure by age 40 years. Female patients are generally less severely affected, with approximately 12% reaching end-stage renal failure by age 40 years and 30% by age 60 years. Age at the development of renal failure tends to run true within families, although exceptions are well documented. Persistent microscopic hematuria is found early in all affected male patients. Most female patients have intermittent microscopic hematuria. Macroscopic hematuria occurs in up to 70% of male patients and 33% of female patients, often at the time of a respiratory infection. Proteinuria develops in male patients with age and reaches nephrotic range in approximately 30%. Sensorineural hearing loss is progressive, starting with high frequencies, and affects male patients more than female patients. It is not, however, present in all families with Alport syndrome. Eye abnormalities are found in approximately 50% of patients with Alport syndrome. These abnormalities include anterior lenticonus, retinal abnormalities, and corneal ulcerations.

Male and female patients are equally affected in autosomal-recessive Alport syndrome. The course is similar to that of male patients with X-linked Alport syndrome. Approximately two-thirds of patients with the autosomal-recessive form develop hearing loss. Approximately one-half of the carriers of the abnormal gene also have microscopic hematuria (see this chapter's discussion of TBMN).

### **Laboratory Findings**

Laboratory findings reflect the degree of renal impairment and may vary from normal early in the disease to advanced renal failure as the disease progresses. Blood urea nitrogen and creatinine levels become elevated with advancing disease. Serum electrolytes may become abnormal, and hypoalbuminemia may develop in select patients who develop nephrotic syndrome. Serum complement values usually are normal. A renal biopsy may help establish the diagnosis in patients in whom the family history is unclear or in those who have a new mutation.

### **Course**

The disease is progressive in male patients and some female patients with X-linked Alport syndrome, and in patients of both sexes with autosomal-recessive and autosomal-dominant forms of Alport syndrome. Proteinuria is not present initially but usually develops later in the course of the disease. Hearing loss is not present at birth. The course is usually similar for members of an affected family, although variations in the progression have been reported.

### **Treatment**

Treatment is supportive, with medical management of hypertension and the complications of renal insufficiency. Dialysis or transplantation is instituted when medical management is no longer sufficient. Audiologic screening can identify hearing impairment early and allow for the timely implementation of hearing augmentation services. Some studies have shown short-term efficacy of cyclosporine, angiotensin-converting enzyme inhibitors, or receptor blockers to control proteinuria in Alport syndrome, although the impact on renal survival with these therapies remains unclear.

### **Prognosis**

In affected individuals, renal disease and hearing loss are progressive. Families carrying mutations consisting of large deletions or stop codons leading to truncated proteins may be at risk for more severe disease than those with mutations leading to an amino acid substitution. Dialysis and transplantation are offered when end-stage renal failure occurs. About 15% of patients with Alport syndrome receiving a kidney transplant develop anti-GBM antibodies (to previously absent collagen subunits), leading to loss of the transplanted kidney in 3% of these cases.

### **Nephritis of Systemic Lupus Erythematosus**

SLE is an autoimmune disease that affects multiple organ systems and is seen mainly in young women during the childbearing years. Twenty percent of cases, however, involve children. (See Chapter 324, Rheumatologic Diseases, for a full discussion.)

### **Etiology**

The cause of SLE is unknown. Dysregulation of the cellular and humoral branches of the immune system occurs and results in an autoimmune state, with autoantibody production and the deposition of circulating immune complexes or the formation of immune complexes in situ. Complement proteins are activated and lead to damage to the glomeruli. Clearly, however, other factors are involved in disease production as well. Female sex predisposes the patient to the development of SLE. There also seems to be a genetic predisposition, with increased evidence of autoimmune phenomena within these families. Blacks and Asians seem to be disproportionately affected. Some cases are related to inherited deficiencies of early components of the complement cascade.

### **Pathologic Features**

Renal histologic findings vary greatly in patients with lupus nephritis. The revised classification system of renal disease in lupus nephritis by the International Society of Nephrology and the Renal Pathology Society is now widely used for interpreting the renal biopsy findings and guiding therapy in this disease. There are 6 classes of disease. It is important to remember that the renal histology may change over the course of disease. Patients may exhibit resolution, progression, and even change in histology. Classes I and II represent mild disease. Focal proliferative (class III)

and diffuse proliferative (class IV) lesions indicate more severe disease and are found in the kidney biopsies of more than one-half the children with lupus nephritis. Class V lupus nephritis, also called *membranous nephritis*, shares many features with idiopathic membranous nephropathy and portends a guarded prognosis. Depending on the class of lupus nephritis, the physician may observe various degrees and combinations of histologic abnormalities. Immunofluorescence microscopy demonstrates deposition of immunoglobulins and complement components in the mesangium and along the capillary loops. Dense deposits, corresponding to the immune complexes detected by immunofluorescence, are seen by electron microscopy. Cellular proliferation and basement membrane thickening are also seen.

### Clinical Presentation

Children with SLE may present with multisystem symptoms, including fever, neuropsychiatric manifestations (eg, malaise, emotional lability), malar erythema, photosensitivity, Raynaud symptoms, myositis, multiple joint arthritis, pericarditis, or pleuritis. Initial complaints may be vague, and a high index of suspicion is warranted. However, childhood SLE tends to be more severe at presentation than adult-onset SLE. Up to 75% of children will have some evidence of renal involvement on presentation. Renal involvement usually progresses with time in most children with SLE and is an important cause of morbidity and mortality. When present, renal involvement may be characterized by isolated hematuria, hematuria with proteinuria, nephrotic syndrome, hypertension, or rapidly progressive renal failure.

### Laboratory Findings

Antinuclear antibodies (ANAs) are positive in most children with SLE. Anti-dsDNA is positive in many patients with renal involvement as well. Serum complement components are frequently decreased, and similar to ANA and anti-dsDNA, these levels tend to correlate with general disease activity. However, renal progression may not correlate with changes in any of these serologic markers. Evidence of renal disease may be characterized by elevation of serum urea and creatinine levels and decrease in serum albumin levels, the latter in the setting of nephrotic-range proteinuria. Findings on urinalysis vary greatly and range from isolated hematuria to hematuria with proteinuria, to nephrotic-range proteinuria. Pyuria is common and reflects the underlying glomerular inflammation. Red blood cell, white blood cell, and renal tubular epithelial cell casts frequently are seen.

Hematologic abnormalities include Coombs-positive anemia, leukopenia, and thrombocytopenia. Antiphospholipid antibodies are found in as many as 67% of children with SLE and are a risk factor for thrombotic complications.

### Course

The course of SLE varies considerably. Renal manifestations can wax and wane with changes in disease activity, intercurrent illness, and type of therapy. In addition to the risk for morbidity and mortality from

the underlying disease, children with SLE are at risk for complications related to treatment and are at increased risk for infectious complications.

### Treatment

Treatment of lupus nephritis should be tailored according to clinical and pathologic manifestations. A renal biopsy should be performed in any patient with persistent hematuria or significant proteinuria and before therapy is begun. Treatment is divided into induction and maintenance phases. High-dose corticosteroid therapy has been the mainstay of treatment of lupus nephritis, although it is accompanied by considerable morbidity. Pulse methylprednisolone is used for the initial treatment of rapidly progressive lupus glomerulonephritis. Oral or pulse-intravenous cyclophosphamide frequently is recommended for the treatment of class III, class IV, and sometimes class V renal disease. Mycophenolate mofetil has shown promise as a remission-inducing agent substituting for cyclophosphamide, thus preventing the significant side effects, particularly its effects on fertility. This circumstance is especially important for young women of childbearing age, given the prevalence of SLE in this population, although the risk for infertility is higher in males and with oral cyclophosphamide therapy. Azathioprine and mycophenolate mofetil have been used as steroid-sparing agents in the maintenance of treatment. Cyclosporine and tacrolimus have been used to induce remission and in maintaining remission, although there is a high risk for relapse on discontinuation of these agents. B-cell depletion with rituximab and plasma exchange are used in severe and refractory patients. Hydroxychloroquine is used for management of extrarenal manifestations of lupus as well as to maintain remissions. Angiotensin-converting enzyme inhibitors or angiotensin receptor blockers should be used to control hypertension and decrease proteinuria. Anticoagulation is indicated in children with thrombotic complications of lupus.

The danger of overwhelming sepsis among these immunosuppressed patients is constant. The effectiveness of therapy is indicated by changes in serologic parameters, blood chemistries, urinary protein quantitation, and complement levels. Care of the patient who has SLE is a highly specialized endeavor that requires knowledge of current treatment modalities, the availability of highly specialized tests, and the necessary resources to care for a patient who has a chronic, severe, life-threatening illness for which treatment with steroids often is disfiguring. These patients are managed best by a team trained in dealing with all aspects of this disease.

### Prognosis

Overall survival of children with SLE seems to have improved over the past several decades, with survival rates up to 95% to 100% at 5 years and 94% at 11 years. However, end-stage renal disease developed in 9% at 11 years of follow-up. Patients with diffuse proliferative lesions on biopsy have the poorest renal outcome. In addition, sclerosis on biopsy specimens, hypocomplementemia, decreased renal function, nephrotic

range proteinuria, and persistent hypertension portend a poor renal prognosis.

### Membranoproliferative Glomerulonephritis

The group of disorders classified as membranoproliferative glomerulonephritis (MPGN) have been reconsidered based on reinterpretation of findings seen by immunofluorescence microscopy (IFM) and as new information about the likely pathogenesis of these diseases has been elucidated. A new classification has been proposed that now refers to idiopathic MPGN (those immune complex-mediated diseases, formerly MPGN types I and III, with immunoglobulin present by IFM) and the C3 glomerulopathies, which include dense deposit disease (DDD, formerly MPGN type II) and C3 glomerulonephritis (C3GN, formerly MPGN types I and III, but lacking immunoglobulin staining by IFM). All are chronic inflammatory diseases of the kidney with a poor prognosis.

### Etiology

Based on new understanding regarding factors likely involved in the pathogenesis of MPGN and the C3 glomerulopathies, DDD and C3GN, it has been proposed that these disorders now be classified based on whether the classical or alternative pathways of complement are activated. The finding of both immunoglobulin and complement fragments in glomeruli by IFM suggests that immune complexes activate the classical pathway of complement and cause glomerular inflammation, resulting in the histopathologic pattern of MPGN type I or III. MPGN type I can be idiopathic or secondary to systemic disorders or infectious agents. Among the infectious agents, hepatitis C viral infection is an important cause worldwide. In children, however, the idiopathic form is more common.

In contrast, unregulated activation of the alternative pathway of complement seems to be important in the pathogenesis of the C3 glomerulopathies (C3GN and DDD). Indeed, in many cases of the C3 glomerulopathies, deactivating mutations have been identified in the complement regulatory proteins—factor H, factor I, factor H-related protein 5, and membrane cofactor protein—that normally keep complement-mediated inflammation in check, as well as mutations in complement factors C3 and B, causing them to be resistant to inactivation by the complement regulatory factors. In addition, C3 nephritic factors, autoantibodies directed against and stabilizing the alternative pathway of complement convertases (protein complexes that further activate the complement system) may be present and render the convertases resistant to the regulatory activity of factor H. These abnormalities are expected to lead to ongoing unregulated activation of the alternative pathway of complement, resulting in deposition of complement components without immunoglobulin in the glomeruli, with resulting inflammatory injury.

Depending on the pattern of these deposits shown by electron microscopy, the diagnosis of DDD (deposits in the mesangium and within the glomerular basement membrane) or C3 glomerulonephritis (mesangial, subendothelial, subepithelial, with or without intramembranous deposits) is made.

### Pathologic Features

Classically, 3 types of MPGN have been described based on pathologic appearance and ultrastructural abnormalities of the GBM. MPGN types I, II (DDD), and III patterns account for 44%, 20%, and 36% of cases, respectively. All 3 types have increased mesangial cellularity and matrix with thickening of glomerular capillary walls, duplication of glomerular basement membranes, and deposits within or around the GBM. All show deposition of complement components in the glomeruli as seen by IFM. As mentioned earlier, complement deposition without immunoglobulin staining by IFM allows C3GN to be distinguished from MPGN types I and III. By electron microscopy, type I and C3GN are characterized by subendothelial and mesangial electron-dense deposits. DDD, formerly MPGN type II, has a more variable presentation by pathology, with only 25% of kidney biopsy specimens demonstrating a typical MPGN morphology, others being mesangial, endocapillary, and crescentic glomerulonephritis. All forms of DDD have thickening and deposits within the GBM. In MPGN type III and C3GN with this pathologic pattern, deposits are present most prominently in the subepithelial space but also are observed on the subendothelial side of the GBM, as well as within the GBM.

### Clinical Presentation

The type I pathologic pattern is the most common of the 3. The average age of onset of primary MPGN in children is 10 years. Children with MPGN can present with asymptomatic hematuria and proteinuria detected on routine screening urinalysis, gross hematuria, nephritis, or nephrotic syndrome. Hypertension and decreased renal function may be present, although the presentation may vary according to the histologic subtype.

Patients with acquired partial lipodystrophy often have circulating nephritic factors and low C3 blood levels. Twenty percent develop DDD.

### Laboratory Findings

At presentation, blood urea nitrogen and creatinine values may be elevated, and albumin may be low in severe cases. Anemia is common. Electrolyte disturbances reflect the presence of renal insufficiency. The serum C3 level is depressed in 67% to 75% of patients on presentation. The serum C4 level is also often low in MPGN type I. Nephritic factors are found in 80% of patients with DDD and in up to 50% with C3GN. Liver function studies may be abnormal in cases related to viral hepatitis. Evidence of hepatitis B virus, hepatitis C virus, and HIV infection should be sought. Cryoglobulins may be elevated in cases of hepatitis C infection. Urinalysis most commonly features hematuria and proteinuria. Proteinuria may reach the nephrotic range. Blood lipid levels are often elevated in the presence of heavy proteinuria. Hematuria may be macroscopic. Cellular casts are a common finding. Quantification of urinary protein excretion is helpful for monitoring the course of the disease and can be achieved by 24-hour urine collection or by following the total protein and creatinine levels on spot urine samples. Definitive diagnosis of

MPGN or the C3 glomerulopathies can only be made by kidney biopsy.

### Course and Prognosis

The long-term outcome of MPGN is typically poor, with progressive loss of renal function. Fifty percent of patients reach end-stage renal failure within about 11 years of diagnosis, and 90% do so within 20 years. Clinically, nephrotic-range proteinuria, renal insufficiency, and hypertension predict progression of disease. On renal biopsy, necrosis, sclerosis, and tubulointerstitial fibrosis are poor prognostic indicators. Type I MPGN has a better prognosis than the other 2 types. Progression of secondary forms of MPGN type I may be halted if the underlying cause can be addressed. Outcome data on the subset of patients with C3GN are not yet available. There is a high risk for recurrence after renal transplantation.

Over time, patients with DDD may develop retinal deposits (drusen) seen on ophthalmologic examination. Visual impairment can develop in 10% of patients.

### Treatment

The goal of treatment is to induce a reduction in proteinuria and inflammation and control hypertension. However, treatment is challenging, and the optimal therapy is controversial because rigorous randomized controlled trials are lacking. Therapy with blockers of the renin-angiotensin-aldosterone system with angiotensin-converting enzyme inhibitors or angiotensin receptor blockers to reduce proteinuria and control hypertension should be strongly considered. In children, the most experience reported regarding immunosuppressive treatment of this disorder has been with high-dose, long-term, alternate-day prednisone therapy. Cumulative renal survival of 82% at 10 years and 56% at 20 years have been reported with this therapeutic approach. Some differences in the clinical course and response to treatment may be seen according to the type of MPGN. Other therapies that have shown promise in small groups of patients include cyclophosphamide, mycophenolate mofetil, and calcineurin inhibition with cyclosporine or tacrolimus. These agents have generally been used in combination with corticosteroids. Plasma exchange may be considered in children with documented deficiency of the regulatory protein complement factor H. Anticomplement factor 5 therapy with eculizumab has shown some promise in improving outcomes in some patients with C3 glomerulopathy in small trials.

## INTERSTITIAL NEPHRITIS

Inflammation of the tubules and interstitium of the kidney is an underappreciated cause of AKI. Acute tubulointerstitial nephritis (AIN) has been found in up to 25% of kidney biopsies performed for AKI in adults. The most common presenting signs are unexplained AKI, proteinuria, leukocyturia, and microscopic hematuria. Fever and eosinophilia are seen in only about one-third of patients, and rash in 20%. Although the definitive etiologic agent is often elusive, AIN is most commonly linked to an immune

reaction to drugs, especially antibiotics and nonsteroidal anti-inflammatory drugs. Less common triggers are bacterial, viral, or parasitic infections or systemic autoimmune disorders such as SLE. Idiopathic forms of AIN are associated with anti-tubular basement membrane autoantibodies. Uveitis can be seen with idiopathic AIN and may precede, occur simultaneously with, or follow the onset of renal disease. Prompt ophthalmologic evaluation and treatment are important to preserve vision. Kidney biopsy is needed to confirm the diagnosis of AIN. Interstitial edema with patchy or diffuse cellular infiltrates composed of T lymphocytes, macrophages, eosinophils, and plasma cells are seen on pathologic specimens. Glomeruli are generally normal appearing in AIN, although interstitial inflammation may be seen with primary glomerular diseases, in which case its presence portends a worse prognosis. Irreversible interstitial fibrosis is seen in more severe cases of AIN and may develop within 1 week of disease onset. Treatment consists of eliminating the inciting agent if it can be identified. The role of corticosteroids in the management of AIN is controversial, although some studies suggest that early treatment may shorten the disease process, and in some cases early treatment may improve long-term outcome.

### WHEN TO REFER

- Acute glomerulonephritis with significant complications
- Acute glomerulonephritis that is not following a typical course expected of poststreptococcal glomerulonephritis
- Failure of complement level to normalize within 6 to 8 weeks in suspected acute glomerulonephritis
- Rapidly progressive course
- Glomerulonephritis with the development of nephrotic syndrome
- Persistent hematuria and proteinuria
- Persistent hypertension
- Elevated creatinine level for age
- Family history of renal failure or deafness
- Any chronic glomerulonephritis

### WHEN TO ADMIT

- Severe hypertension
- Renal failure with significant electrolyte disturbances
- Congestive heart failure from volume overload
- Oliguria or anuria
- Rapidly progressive renal failure

**Chapter 295****NEPHROTIC SYNDROME**

William S. Varade, MD

Nephrotic syndrome (NS) is defined by the clinical findings of heavy proteinuria, hypoalbuminemia, edema (often to the point of frank anasarca), and hyperlipidemia. Many causes of NS exist, and the most likely cause varies by age. NS may be the result of an underlying systemic disease, or it may manifest as a primary idiopathic renal disorder. Examples of causes of primary and secondary NS in children are listed in Box 295-1. The overall outcome depends on the etiology, and ranges from complete remission

**BOX 295-1 Examples of Primary and Secondary Causes of Nephrotic Syndrome in Children**
**PRIMARY NEPHROTIC SYNDROME**

- Minimal change nephrotic syndrome
- Focal segmental glomerulosclerosis
- Diffuse mesangial hypercellularity
- Membranoproliferative glomerulonephritis
- Membranous nephropathy

**SECONDARY NEPHROTIC SYNDROME**

- Inherited diseases (congenital nephrotic syndrome, diffuse mesangial sclerosis, Alport syndrome, nail-patella syndrome, Lowe syndrome)
- Vasculitides (lupus nephritis, Henoch-Schönlein purpura nephritis, Wegener granulomatosis, Goodpasture syndrome)
- Postinfectious (poststreptococcal, HIV, hepatitis B and C, malaria, syphilis, intrauterine infections, other viruses and bacteria)
- Drugs and toxins (nonsteroidal anti-inflammatory drugs, gold)
- Diabetes mellitus (rare in children)

with no long-term sequelae to inexorable progression to end-stage renal failure. Newer treatments offer alternatives for patients with resistant forms of NS or who experience significant side effects from first-line treatments, although such treatments themselves carry the potential for significant morbidity.

**EPIDEMIOLOGIC FEATURES**

The annual incidence and prevalence of idiopathic NS in children are estimated to be 2 and 16 cases per 100,000 children, respectively. The incidence is 10-fold lower in adults. The male-to-female ratio is reported to be 2:1 for children and 1:1 in adolescents and adults. Early studies in the 1960s and 1970s showed that in children with NS from 3 months to 16 years of age, 76% had minimal change nephrotic syndrome (MCNS), 7% had focal segmental glomerulosclerosis (FSGS), 2% to 5% had diffuse mesangial hypercellularity or mesangial proliferation, and 7% had membranoproliferative glomerulonephritis (MPGN). Only 1% of children had membranous nephropathy, which is in contrast to adults with NS, in whom 22% had MCNS, 12% had FSGS, 20% had membranous nephropathy, and 25% had proliferative lesions.

Occurrence of MCNS peaks between 2 and 5 years of age. Eighty-seven percent of children with NS between the ages of 3 months and 6 years have MCNS, and 92% of these will experience remission of their disease when treated with a course of prednisone. However, subsequent studies have suggested a higher incidence of FSGS in children and adults more recently, with FSGS accounting for up to 25% of diagnoses in children who undergo biopsy for NS, although others dispute this. Adolescents are more likely to have a more aggressive cause, such as FSGS, MPGN, or membranous nephropathy, than younger children.

Racial differences are seen in the incidence of underlying histopathologic disorders and prognosis in nephrotic patients. Black and Hispanic adolescents are more likely than white adolescents to have FSGS and to progress to end-stage renal disease. In a predominantly black and Hispanic population of adolescents with NS, 55% had FSGS, 20% had MCNS, and 7% had MPGN.

**EVALUATION****Clinical Presentation**

Typically, children with NS (Figure 295-1) gradually develop edema and an inappropriate weight gain, although cases associated with glomerulonephritis may have a more acute onset, with signs and symptoms of nephritis predominating. The presence of periorbital edema when arising in the morning that resolves during the course of the day is often mistaken for allergy. Clothing may be tight, and socks may leave indentations in the skin of the shins and ankles. The abdomen may be distended, and a fluid wave may be discernible on examination. Breath sounds may be decreased at the lung bases because of accumulation of pleural fluid. Although intravascular volume is low in most children with NS, in

some children, it may be increased. These children may have a gallop on auscultation of the heart, rales over the lung fields, and hepatomegaly. Boys may develop significant scrotal swelling, and girls may develop labial swelling (Figure 295-2). The child or parents may report decreased frequency of urination and the passage of dark, amber-colored, concentrated-appearing urine that seems to foam when voided. Overall, 16% of children with NS have hypertension at presentation. The presence of marked hypertension should suggest the possibility of underlying glomerulonephritis.

**Figure 295-1** A 2-year-old girl with nephrotic syndrome.

**Figure 295-2** Severe labial edema in a 3-year-old girl with nephrotic syndrome.

### Laboratory Evaluation

Laboratory evaluation begins with a urinalysis in the child with edema. This evaluation will demonstrate significant proteinuria in cases of NS. Up to approximately 25% of children who have primary NS will also have 3 to 5 red blood cells per high-power field on urinalysis. The presence of significant microscopic hematuria or gross hematuria suggests that NS might be the result of an underlying nephritic process. The presence of glycosuria in untreated children with NS suggests underlying tubular injury that may be seen with FSGS. Blood urea nitrogen and creatinine values are generally normal or only slightly increased in primary NS. Serum albumin level is low. Mild hyponatremia may be present because of water retention. Total calcium levels are low because of the low serum albumin level, but ionized calcium levels are usually normal. The serum cholesterol level is usually increased. The third component of complement (C3) is generally normal. A lowered level suggests MPGN, poststreptococcal glomerulonephritis, or lupus nephritis. Antinuclear antibody should be tested in older children or those with signs suggestive of systemic lupus erythematosus. Since hepatitis B, hepatitis C, and HIV are associated with certain forms of NS, serology should be determined for these viruses. Chest radiographs will usually show a small cardiac silhouette and, in severe cases, the presence of pleural fluid. Cardiomegaly may be seen in patients with increased intravascular volume.

Urinary protein losses can be quantified with a 24-hour urine collection or estimated with a urine protein-to-creatinine ratio on a first morning urine sample. Nephrotic-range proteinuria is defined as (1) urinary protein excretion on a timed urine collection of more than 3.5 g/day in adults or more than 40 mg/m<sup>2</sup>/hour or 1 g/m<sup>2</sup>/day in children, or (2) a urine protein-to-creatinine ratio (mg/mg) of more than 2 on a random urine sample. Urinary protein quantification is not critical in the management of NS, with heavy proteinuria demonstrated by dipstick determination and with a typical clinical presentation. It is more helpful for monitoring partial response to treatment of children with resistant forms of NS.

Kidney biopsy is recommended for older children who are at higher risk for etiologies of NS other than minimal change disease.

For children with steroid-resistant NS the place of genetic testing for mutations of genes encoding proteins involved in podocyte structure and function (*NPHS1*, *NPHS2*, *PLCE1*), as well as the transcription factor Wilms tumor (WT1), may be considered.

### PATHOPHYSIOLOGIC FEATURES

The glomerular capillary wall acts as a selective filtration barrier composed of the glomerular capillary endothelial cell with its covering glycocalyx, the glomerular basement membrane, and the podocytes of the glomerular visceral epithelial cells. Slit diaphragms connect adjacent podocytes. This filtration barrier normally possesses a net negative electrical charge and behaves functionally as though narrow pores are present. All 3 layers of the glomerular basement membrane seem to contribute to these

characteristics, which serve to prevent the passage of proteins into the urine. In NS, these barriers are variably altered, depending on the severity and nature of the underlying disease process. Examples of alterations in the filtration barrier include the loss of negative charge seen in MCNS, the altered organization of glomerular basement membrane components in Alport and Pierson syndromes, or mutations of genes encoding proteins associated with glomerular podocytes, leading to alterations in podocyte structure and function. The changes in the barriers allow the passage of large quantities of plasma proteins into the urine, which, in turn, may lead to a decrease in the level of proteins in the blood.

Classically, the development of edema has been explained by massive losses of plasma proteins, in particular albumin, in the urine, with the consequent development of hypoalbuminemia, which leads to decreased plasma oncotic pressure and leakage of fluid from the vascular space into the interstitium. The subsequent drop in the circulating blood volume stimulates the renin-angiotensin-aldosterone system, leading to avid sodium retention, and it produces a nonosmotic stimulus for vasopressin secretion and free-water reabsorption. The result of these responses is the development of massive tissue edema with the excretion of a decreased volume of concentrated urine. However, this scenario does not explain the edema formation in all nephrotic patients. Studies have demonstrated that, in patients who experience remission, diuresis often begins as the proteinuria is resolving, but before normalization of plasma albumin levels. In addition, primary sodium retention has been demonstrated with the onset of proteinuria (but before the development of hypoproteinemia) in at least some patients experiencing a relapse of NS. This circumstance would then lead to expansion of vascular volume and the development of edema.

## COMPLICATIONS

### Infection

Morbidity and mortality were high in NS before the introduction of corticosteroid and antibiotic therapy. Infection was the leading cause of death in children. Infectious complications include spontaneous bacterial peritonitis, sepsis, cellulitis, and pneumonia. Streptococcal pneumonia and gram-negative bacteria are responsible for most infections in NS. Predisposing factors for the development of bacterial infections include tissue edema that may facilitate the spread of infection, defective opsonization of invading bacteria caused by loss into the urine of small components of the alternative pathway of complement (complement factor B), and impaired cellular immunity. In addition, the effects of immunosuppressive therapies used in the treatment of NS may increase the susceptibility to infection. Children with recurrent NS should receive 23-valent and heptavalent conjugated pneumococcal vaccination. A role for prophylactic antibiotic therapy has not been established.

### Thromboembolism

Thromboembolic events, such as deep vein thrombosis, pulmonary embolism, renal vein thrombosis,

and dural sinus thrombosis, are well-described complications of NS in children. They are reported to occur less frequently in children than in adults, although the documentation of subclinical pulmonary embolism by radionuclide ventilation-perfusion lung scanning in 28% of children suggests that the true incidence may be underreported. Arterial thrombosis occurs more commonly in children than in adults. Risk factors for development of thromboembolism in children with NS include age 12 years or older at diagnosis and higher degrees of urinary protein loss. Children with thromboembolism are more likely to have secondary as opposed to primary forms of NS. Contributory factors include increased plasma levels of procoagulant factors, urinary loss of inhibitors of coagulation, and thrombocytosis. The predisposition to thrombus formation may be exacerbated by decreased intravascular volume, especially in the face of vigorous forced diuresis.

### Hyperlipidemia

Elevation of plasma lipids in NS has classically been said to result from increased hepatic lipoprotein synthesis caused by generalized increased hepatic protein synthesis in response to a lowered plasma albumin level. The mechanism behind the increase in plasma lipids is probably more complex than this and may involve production of inflammatory cytokines, leading to, or at least associated with, alterations in lipid synthesis, catabolism, and recycling. In severe disease with heavy proteinuria, lipoprotein lipase activity may be decreased, leading to decreased lipolysis and resulting in high triglyceride levels. The return of high cholesterol levels to normal at remission of NS often lags behind the normalization of serum albumin levels. In unremitting NS, increased plasma lipids may contribute to cardiovascular morbidity, and treatment of lipid abnormalities should be considered.

## SPECIFIC HISTOPATHOLOGIC ENTITIES ASSOCIATED WITH PRIMARY NEPHROTIC SYNDROME OF CHILDHOOD

### Minimal Change Nephrotic Syndrome

MCNS, also known as *lipoid nephrosis* and *nil* (nothing in light microscopy) *disease*, is the most common pathologic diagnosis in children with NS; 92% will experience remission with a course of corticosteroids. Hematuria is found in approximately 13% and hypertension is found in 10% to 20% of cases. Relapses are common, but the long-term prognosis is excellent. Relapses tend to become less frequent with age, and the disorder usually resolves around the time of puberty without permanent renal impairment. The diagnosis is assumed in most children because biopsy is generally not performed in those who follow a typical course and who respond to corticosteroid therapy. These children should more correctly be considered to have the clinical diagnosis of steroid-responsive idiopathic NS of childhood, which encompasses a variety of histopathologic diagnoses.

Investigators have proposed that MCNS may be an immune-mediated disease. Evidence supporting this theory includes the response of MCNS to immunosuppressive therapy, an association with allergens, an association with lymphomas, the presence of altered T-lymphocyte function, and the description of various circulating factors, immunomodulatory substances, permeability factors, and lymphokines.

The histopathology of MCNS shows minimal abnormalities by light microscopy. Most pathologists allow for a small amount of mesangial hypercellularity within this classification. Immunofluorescence is negative for immunoglobulin and complement. Electron microscopy shows diffuse fusion of the glomerular epithelial cell foot processes.

### Focal Segmental Glomerulosclerosis

FSGS is found as both an idiopathic and a secondary pathologic diagnosis. Secondary forms are thought to represent a final common pathway to glomerular epithelial cell injury, glomerular adaptation to significant nephron loss with glomerular hypertension or hyperfiltration, inherited abnormalities of the glomerular basement membrane, or severe glomerulonephritis. Disease processes that can be associated with FSGS lesions include diabetic nephropathy, sickle cell disease, HIV nephropathy, and glomerulonephritides such as immunoglobulin A (IgA) nephropathy, MPGN, and lupus nephritis.

Children with idiopathic FSGS tend to be older, and blacks are disproportionately affected. The prognosis of FSGS is more guarded; complete remission is achieved in only one-fourth of children treated with corticosteroids. Many are steroid resistant or dependent from the time of initial treatment, or they become steroid resistant over time. Hematuria may be found in 50% or more, and hypertension in approximately 50% of cases. Up to 50% may progress to end-stage renal disease with time, and a subgroup will progress rapidly within 3 years of presentation. FSGS recurs in up to 40% of patients reaching end-stage renal failure who receive a renal transplant.

Primary FSGS may actually be the manifestation of a systemic disorder. Evidence for this view includes the following: (1) the disease may recur in transplanted kidneys, (2) proteinuria could be induced in animals by infusion of serum from a patient with recurrent FSGS, (3) recurrent FSGS in transplanted kidneys may respond to plasmapheresis, and (4) a circulating factor capable of increasing the permeability of isolated glomeruli to albumin has been demonstrated in the serum of some patients with recurrent FSGS.

The histopathology of FSGS is characterized by the presence of scars affecting portions or segments of some, but not all, glomeruli. Mesangial hypercellularity, tubular atrophy, and interstitial fibrosis are often present. Weak mesangial and segmental deposits of C3 and immunoglobulin M (IgM) can be seen by immunofluorescence, but probably represent nonspecific trapping of these proteins. Electron microscopy may show widespread effacement of foot processes and separation of glomerular epithelial cells from the underlying basement membrane. Different variants of

FSGS have been described that may reflect different stages of disease development, pathogenesis, and prognosis.

### Membranoproliferative Glomerulonephritis

MPGN is a chronic inflammatory disease of the kidney with a poor prognosis. It is discussed in more detail in Chapter 294, Nephritis. The average age at onset of primary MPGN is approximately 9 years. Between 50% and 67% of patients develop NS, and some of these patients may not have significant hematuria. The serum C3 level is low in 67% to 75% of patients.

### Membranous Nephropathy

Membranous nephropathy is a chronic glomerular disease that can also be idiopathic or the result of a systemic disorder. Secondary causes have been reported to be more common in children with membranous nephropathy than in adults. Important causes include hepatitis B and hepatitis C infections, certain drugs, systemic lupus erythematosus, malignancies, and bone marrow and renal transplants. It can affect any age group, but is rare in children and adolescents; it is responsible for only approximately 1% of children with NS. At presentation, up to 75% of children with membranous nephropathy have NS, most have microscopic hematuria, and 37% have hypertension. As many as 40% of children develop gross hematuria. Complement protein levels are usually normal. Spontaneous remissions occur in most patients, but remission may not occur for several years after onset. From 18% to 25% of affected children develop chronic kidney disease. Poor prognostic factors include persistent heavy proteinuria, hypertension, elevated serum creatinine, and significant scarring on biopsy.

By light microscopy, membranous lesions are seen as diffuse thickening of the glomerular capillary walls. Capillary lumens are patent, and little mesangial proliferation is found. Silver-stained biopsy specimens show spikes of basement membrane material projecting on the subepithelial side of the glomerular basement membrane. By electron microscopy, glomerular capillary walls are thickened by subepithelial electron-dense deposits and projections (spikes) of the lamina densa. The extent of these projections with relation to the deposits forms the basis for classifying the stages of membranous nephropathy. Immunofluorescence studies show granular deposits of immunoglobulin G (IgG) and the third component of complement along the glomerular basement membrane.

### Genetic Causes of the Nephrotic Syndrome

Mutations of certain genes, especially those intimately associated with glomerular epithelial podocytes or the glomerular basement membrane, have been implicated in the development of hereditary forms of NS.

*Congenital nephrotic syndrome* refers to NS presenting in the first 3 months of life. Pathologically, it may be a Finnish-type congenital NS diffuse mesangial sclerosis, FSGS, minimal change disease, or membranous nephropathy. Secondary forms may

be caused by congenital infections, heavy metal exposure, or genetic syndromes, among other more uncommon associations. Congenital NS of the Finnish type is an autosomal-recessive disorder caused by mutations in the *NPHS1* gene encoding nephrin, a protein found in the slit diaphragms between adjacent podocytes, or the *NPHS2* gene encoding podocin, a podocyte membrane protein. Less common syndromic forms are caused by mutations in the Wilms tumor suppressor gene (*WT1*), the laminin  $\beta_2$  gene, and others.

Infants are often premature and small for gestational age. The placenta is markedly enlarged, and amniotic levels of  $\alpha$ -fetoprotein are high. Edema often becomes evident within days of birth. Prognosis of congenital NS depends on the underlying cause. It is guarded for congenital NS of the Finnish type with significant morbidity and mortality from complications, particularly malnutrition, infection, and thrombotic events caused by the massive protein losses. Treatment is supportive, but must be aggressive, and it may include intensive nutritional support and nephrectomies to stem the protein losses and maintain the patient on dialysis until kidney transplantation can be performed.

*Diffuse mesangial sclerosis* may be isolated or part of Denys-Drash syndrome, consisting of onset of NS before 2 years of age with rapid progression to end-stage kidney failure, male pseudohermaphroditism, and Wilms tumor. The isolated form is most commonly caused by mutations of the *PLCE1* gene, whereas the Denys-Drash syndrome is associated with mutations of the *WT1* gene. Support until kidney transplantation is required for the renal disease while the risk for or actual presence of Wilms tumor is addressed. Mutations in *WT1* may also be seen in patients with Frasier syndrome, consisting of male pseudohermaphroditism and FSGS.

Nephrin and podocin mutations have also been found in steroid-resistant, autosomal-recessive, and sporadic cases of FSGS in infants and older children, with a rapid progression to renal failure. *PLCE1* and *WT1* mutations may also be associated with some cases of sporadic FSGS. Mutations in the *ACTN4* gene encoding  $\alpha$ -actinin, a podocyte protein that associates with actin filaments of the cytoskeleton and slit diaphragms, results in an autosomal-dominant form of FSGS with onset during early childhood and slow progression to renal failure. Variants of the apolipoprotein L1 (*APOL1*) gene have been associated with increased risk for FSGS and progression to end-stage kidney disease in blacks.

## MANAGEMENT

Nephrotic syndrome occurring in the first 2 years of life should be evaluated and managed with a pediatric nephrologist.

Although a great deal of attention has been paid to the underlying pathologic diagnoses in idiopathic NS occurring in childhood, the clinical response to a course of corticosteroids seems to be as informative in determining long-term outcome as the underlying

histopathology. Initially, 85% of children will respond to a trial of prednisone; 94% will have responded by 4 weeks of initiating therapy. Most corticosteroid-responsive patients have MCNS. However, up to 25% of corticosteroid-resistant patients are found by biopsy to have MCNS, while 5% to 10% of the corticosteroid-responsive patients have FSGS. Biopsy findings do not predict which children who have MCNS will be corticosteroid resistant or which children who have FSGS will be corticosteroid responsive. In general, patients who achieve a remission on steroids, whether they have MCNS or FSGS, do not progress to renal failure if they remain responsive to corticosteroid therapy.

Children between the ages of 1 and 6 years are most likely to have MCNS, as determined by renal biopsy, and respond clinically to a trial of corticosteroids by experiencing remission. Therefore, treating a child in this age range (or even up to age 12 years) who has the new onset of typical, pure NS with a trial of corticosteroids is now customary. Treatment of the initial episode of NS consists of prednisone at 2 mg/kg/day or 60 mg/m<sup>2</sup>/day (maximum, 60 mg/day) for 6 weeks usually given in divided doses, although some studies suggest that it can be given as a single morning dose with a similar rate of response. This treatment is followed by a single dose of 1.5 mg/kg or 40 mg/m<sup>2</sup> (maximum 40 mg/day) for an additional 6 weeks given in the morning on alternate days. The most recent recommendations call for discontinuation of treatment at this point without taper. A relapse is diagnosed if the first morning urine tests 2+ or greater for protein by Albustix or the urine protein-to-creatinine ratio is greater than 2 for 3 consecutive days. Relapses are usually triggered by intercurrent illnesses or allergies, and parents can be taught to use albumin test sticks or sulfosalicylic acid at home to monitor urinary protein excretion. Relapses are treated with prednisone 2 mg/kg/day or 60 mg/m<sup>2</sup>/day until the urine is trace or negative for protein for 3 consecutive days. The prednisone dose then is changed to 1.5 mg/kg or 40 mg/m<sup>2</sup> on alternate days for 4 weeks.

Approximately 25% of children who experience relapse will follow a frequently relapsing course, defined as 2 or more relapses occurring within 6 months of completing an initial course of corticosteroids or 4 or more relapses within a 1-year period. Children who experience relapse while corticosteroids are being tapered, or within 2 weeks of completing a course of corticosteroids, are considered to be corticosteroid dependent. Children who have both frequently relapsing and corticosteroid-dependent NS are more likely to develop corticosteroid toxicity. Second-tier therapies for difficult cases are listed in Box 295-2. Consideration for treatment with these agents should be made in consultation with a pediatric nephrologist. Alkylating agents, either cyclophosphamide or chlorambucil, can induce a prolonged remission in patients with frequently relapsing NS, and some patients with corticosteroid-dependent NS, although with a risk for significant toxicity. Mycophenolate mofetil has also shown some success as a corticosteroid-sparing agent. Cyclosporine or tacrolimus can be used as a corticosteroid-sparing

### **BOX 295-2 Secondary, Tertiary, and Complementary Therapies for Difficult Cases of Nephrotic Syndrome**

- Cyclophosphamide
- Chlorambucil
- Cyclosporine
- Tacrolimus
- Methylprednisolone infusions
- Levamisole
- Mycophenolate mofetil
- Intuximab
- Angiotensin-converting enzyme inhibitors
- Angiotensin-receptor blockers

agent, although relapse after withdrawal of these agents is common. Rituximab, an anti-B cell monoclonal antibody, is being increasingly used for highly recalcitrant cases with some success.

Children whose disease fails to respond to the initial or subsequent courses of corticosteroids have corticosteroid-resistant NS and thus a more guarded prognosis. Many of these children will have focal segmental glomerulosclerosis as the cause of their NS. Consultation with a pediatric nephrologist should be made for consideration of a renal biopsy and more aggressive treatment. Similarly, children who are outside the usual age range for typical idiopathic NS of childhood, who have refractory edema, or who have complicated NS should be referred to a pediatric nephrologist for help with establishing the diagnosis and choosing a treatment plan. Current treatment regimens for corticosteroid-resistant NS are given in Box 295-2 and include high-dose, long-term intravenous methylprednisolone, cyclosporine, or tacrolimus. Cytotoxic agents, such as cyclophosphamide, have not been as successful in the setting of corticosteroid resistance as the other therapies noted previously.

Complications of corticosteroid therapy include the development of cushingoid features, cataract formation, glaucoma, gastritis, peptic ulcer disease, pancreatitis, hypokalemia, hypertension, increased risk for infection, behavioral changes, hyperlipidemia, bone disease, and growth delay if treatment is prolonged. Growth impairment should lead to consideration of use of steroid-sparing agents. Supplemental vitamin D may prevent some bone loss that can occur, especially early in the course of treatment with steroids, although determination of bone mineral density should be considered in those with prolonged exposure to corticosteroids. Use of gastrointestinal prophylaxis with a proton pump inhibitor should be considered when prescribing high doses of corticosteroids. Cytotoxic agents (eg, cyclophosphamide, chlorambucil) can be associated with increased risk for infection, malignancy, and sterility, but usually only with higher doses

than those typically used for NS or after repeated or prolonged courses. Cyclophosphamide can cause hemorrhagic cystitis. Therefore, a large fluid intake and frequent voiding should be encouraged. Chlorambucil therapy has been associated with induction of seizure activity. Cyclosporine and tacrolimus both have nephrotoxic potential and can cause acute and chronic renal injury. Acute renal failure can occur in severely nephrotic patients who are treated with cyclosporine and who have markedly decreased intravascular volume. Mycophenolate mofetil can cause bone marrow suppression and gastrointestinal upset.

Angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers can be tried in resistant NS, even in the presence of normotension, to decrease urinary protein excretion. ACE inhibitors act by decreasing glomerular capillary pressure and can cause a reversible increase in serum creatinine and hyperkalemia that must be monitored. High doses of ACE inhibitors may decrease progressive sclerosis.

Salt intake should be restricted in edematous children because of their avid sodium retention. Water intake does not usually need to be restricted, especially if sodium intake is adequately limited, unless significant hyponatremia develops or edema is intractable. Diuretics are used judiciously, given the already reduced intravascular volume in most nephrotic patients and the attendant risk for thromboembolism. Furosemide alone or in combination with a thiazide diuretic is used to treat clinically significant edema. Severe edema interfering with ambulation, compromising respiratory status, or causing tissue breakdown can be treated with intravenous albumin followed by intravenous furosemide if renal function and urine output are fairly well maintained. Patients must be monitored closely during infusion for the development of signs of intravascular overload, such as rales, cardiac gallop, and hepatomegaly. This therapy can also be used in the severely edematous, corticosteroid-resistant nephrotic patient in whom cyclosporine therapy is being considered in an attempt to improve renal perfusion and prevent the precipitation of acute renal failure.

Hospital admission should be considered for children during their first episode of NS, especially if complications are present, for teaching the parents home management and monitoring. Children who have severe edema compromising their ventilatory status, causing cardiovascular congestion, or interfering with ambulation should be admitted for forced diuresis. Infectious complications of NS may require treatment with parenteral antibiotics. Hypertension, renal insufficiency, and electrolyte disturbances may also require hospitalization for stabilization. Children with significant renal insufficiency may require dialysis to manage edema, electrolyte disturbances, and uremia.

The treatment of idiopathic membranous nephropathy is controversial with regard to the choice of agent and the timing of intervention. Investigators have suggested that therapy need not be provided in most patients, given the high rate of spontaneous remission. Patients who have evidence of renal insufficiency, persistent heavy proteinuria, hypertension, or

sclerosis on biopsy should be considered for treatment. Agents that have been used for the treatment of membranous nephropathy include high-dose corticosteroids provided orally or intravenously alone or in combination with cytotoxic agents, mycophenolate mofetil, cyclosporine, and rituximab.

### WHEN TO REFER

- Complicated NS
- Outside the expected age range (<2 years or >10 years of age)
- Accompanied by signs of glomerulonephritis (renal insufficiency, hypertension, hematuria, hypocomplementemia)
- Refractory edema
- Frequently relapsing NS
- Corticosteroid-dependent NS
- Corticosteroid-resistant NS

### WHEN TO ADMIT

- Initial episode for teaching of parents
- Anasarca interfering with ambulation or compromising ventilation
- Pleural effusions or ascites interfering with ventilation
- Signs of volume overload (congestive heart failure)
- Infection (eg, severe cellulitis, peritonitis)
- Significant hypertension
- Significant electrolyte abnormalities
- Compromised renal function

## Chapter 296

# NEURAL TUBE DEFECTS

Heidi Castillo, MD

Neural tube defects (NTDs) are a group of congenital anomalies that are the result of failure of the neural tube to close between the third and fourth week of fetal development. Most NTDs can be divided into cranial presentations and spinal presentations. Cranial presentations include anencephaly and encephalocele. The most common spinal presentations include the bony anomaly spina bifida occulta and the combined bony and neural anomalies myelomeningocele, meningocele, myeloschisis, congenital dermal sinus, lipomatous malformations, diastematomyelia, and caudal agenesis. Primary neurulation is the process by which the embryonic notochord and neural plate interact to form the neural tube. This process is complete between 24 and 26 days' gestation. Failure of the neural tube to close during primary neurulation results in anencephaly, encephalocele, and myelomeningocele, the "open" NTDs. Secondary neurulation follows primary neurulation and continues through term gestation. It consists of secondary canalization and retrogressive differentiation of the caudal cell mass that forms at the caudal end of the neural tube. Secondary neurulation is responsible for the formation of the tip of the conus medullaris and filum terminale. Impaired secondary neurulation results in the "closed" NTDs, including diastematomyelia, meningocele, lipomatous malformations, teratomas, dermal sinus tracts, and tethered spinal cord.

In anencephaly, a poorly differentiated brainstem is present, but there is no differentiated supratentorial neural matter. Encephaloceles are characterized by a defect of the skull (usually in the occipital region) that can result in herniation of meninges and brain tissue. These are rare congenital anomalies that are often associated with deformities of the brainstem and skull base along with hydrocephalous.

Spina bifida is a collective term used to describe a group of congenital anomalies of the vertebrae, meninges, and spinal cord (Figure 296-1). Spina bifida occulta refers to incomplete development of the vertebrae, with the spinal cord and overlying skin remaining intact. Spina bifida occulta is the most common type of spina bifida and is seen in up to 15% of the general population. It is most often picked up incidentally on abdominal or spine films. A meningocele is another form of spina bifida in which a cystic sac of cerebral spinal fluid is present into which the meninges protrude; with this type of lesion there is no nerve involvement.

A myelomeningocele is the most severe type of spina bifida. It is characterized by a disruption of the vertebrae with protrusion of both the meninges and spinal cord. A Chiari II malformation is present in most patients with myelomeningocele and is the most common cause of death in infancy. The basic abnormality in Chiari II

**Figure 296-1** Types of spina bifida.

malformation is inadequate development of the fourth ventricle, with a resultant small posterior fossa. This may lead to caudal displacement of the cerebellar tonsils and vermis, caudal medulla, and variably the fourth ventricle into the cervical spinal canal. Patients with Chiari II malformations may also have supratentorial abnormalities, including polymicrogyria, agenesis of the corpus callosum, and aqueductal stenosis, resulting in hydrocephalus. In addition, these patients may have epilepsy, hydrocephalus, and cognitive impairments.

Diastematomyelia is an NTD in which the spinal cord is split along its axis; each hemicord is surrounded by its own dural sac. It is often associated with spina bifida and scoliosis. Lipomatous malformations, the most common of the closed NTDs, occur when excessive lipomatous tissue is within or attached to the spinal cord or the filum terminale. This group of malformations has a variety of presentations that vary in terms of their involvement of the spinal cord. They represent a range of abnormal embryonic development. Included in this group of malformations are lipoma of the filum terminale, lumbosacral lipoma, lipomyelocele, and lipomyelomeningocele. Physical examination with the addition of magnetic resonance imaging (MRI) is key to diagnosing these malformations. Dimples off midline or proximal to the gluteal cleft, abnormal gluteal creases, coarse hair, or hemangiomas are often indicative of a more severe underlying defect and require further investigation.

This chapter will mainly focus on myelomeningocele.

## EPIDEMIOLOGY

It is estimated that the overall prevalence of spina bifida among children and adolescents in the United States is 3.1 cases per 10,000; this represents more than 24,000 children and adolescents living with spina bifida. The overall prevalence of spina bifida is slightly higher among females than males. The prevalence of

NTDs has been shown to vary by race and ethnicity, with the highest rates found among Hispanics and the lowest rates found among blacks and Asians.

Internationally, there is marked geographic variation in the incidence of NTDs. The highest incidence rates worldwide have been observed in the British Isles, where 2 to 3.5 cases of myelomeningocele and anencephaly per 1,000 births have been reported. The lowest incidence rate has been documented in Japan.

Among parents with 1 child with spina bifida or anencephaly, the risk of having a second affected child is approximately 3%. The overall incidence of NTDs has been declining secondary to folic acid supplementation and fortification of food. This decline has also been affected by the choice to terminate pregnancy among those who are prenatally diagnosed.

## ETIOLOGY

Although the exact etiology of NTDs remains unknown, a genetic predisposition does exist. In addition, inadequate intake of folic acid increases the risk of NTDs. As a result of this known link between NTDs and folic acid, periconceptional use of folic acid with a dose of at least 400 mcg per day is universally recommended in all women of child-bearing age. Furthermore, many countries have implemented fortification of grain products with folic acid.

There is an increased risk of NTD among infants of mothers with pregestational diabetes. Maternal use of valproic acid or carbamazepine is also associated with an increased risk of spina bifida.

NTDs can occur as part of malformation syndromes resulting from known chromosomal abnormalities (eg, trisomy 13, 18) and single gene disorders. There is some evidence that suggests, in rare cases, an X-linked autosomal recessive inheritance pattern of certain NTDs. However, most cases are not because of

known chromosomal aberration or to the effects of a mutation in a single genetic locus.

## DIAGNOSIS

### Signs and Symptoms

Many NTDs are diagnosed prior to birth. Screening with maternal serum alpha fetoprotein is most accurate when done between the 16th and 18th week of gestation. Although an elevated value strongly suggests an open NTD (a sensitivity of 75% and a specificity of 97.7%), detection of an open NTD with fetal ultrasound in the hands of a skilled ultrasonographer is highly specific. MRI is obtained at some centers prenatally. It can be used to predict lesion level and to evaluate for intracranial pathology or other structural anomalies.

If not diagnosed antenatally, most open NTDs are apparent upon physical examination. Conversely, closed NTDs may not be apparent at birth. These have variable presentations but often have an associated cutaneous abnormalities including peri-spinal lipomas, hemangiomas or tufts of coarse hair over the defect. Symptoms of a closed NTD that may present later in life can include lower extremity asymmetry, weakness, lower back pain, and bladder or bowel dysfunction. With regard to the Chiari II malformation associated with myelomeningocele, symptoms may occur at any age but most commonly occur in infancy. During this time, disorders of swallowing are the most common clinical manifestations and may include choking on foods and frequent vomiting. Other signs of brainstem dysfunction are repeated aspiration pneumonia, apnea or cyanotic spells, inspiratory stridor, vocal cord paralysis, and a hoarse or high-pitched cry. In older children, signs and symptoms of the Chiari II malformation may include weakness or spasticity of the extremities, headaches caused by hydrocephalus, neck pain, cerebellar dysfunction, oculomotor changes, or scoliosis.

### Diagnostic Approach

A complete neurologic examination is imperative. In particular, head circumference as well as motor and sensory assessments should be detailed upon initial presentation and with subsequent evaluations. It is important to note that the functional motor impairment level does not always correspond to the anatomic level of the lesion as seen on imaging. In addition, the motor function may not be symmetric. Spinal deformity, lower extremity deformity, anal sphincter tone, and urinary stream should also be assessed.

### Laboratory Findings

Urinalysis, urine culture, and serum urea nitrogen and creatinine should be obtained at birth to evaluate renal function. Additionally, these should be repeated routinely, especially for children who have vesicoureteral reflux or any signs or symptoms of a urinary tract infection.

### Imaging

Imaging for central nervous system (CNS) pathology is commenced during the neonatal period and repeated

**Table 296-1** Deep Tendon Reflex Site

DEEP TENDON REFLEX SITE	NERVE ROOT

Achilles	S1-2

as necessary for assessment of the secondary conditions associated with spina bifida. Head computed tomography (CT) scan or ultrasound assist in diagnosing and monitoring hydrocephalus. When a ventricular shunt is present and a shunt malfunction is suspected, a CT scan of the head and radiograph of shunt tubing is essential. Cranial MRI can help the evaluation of a Chiari II malformation and may also reveal any defects in cellular migration in the cerebral cortices. An MRI of the spine can help evaluate for the presence of spinal cord tethering or syringomyelia. A baseline MRI of the brain and spine is helpful for comparison in future investigations, especially in the context of progressive neurologic deterioration.

Throughout infancy and early childhood, patients are followed with routine renal and bladder ultrasounds. Voiding cystourethrograms are performed routinely to assess bladder size, shape, and capacity, and to determine if urethral reflux is present. Urodynamic studies assess the function of the bladder and urethra by assessing pressures; these should be obtained regularly to determine if the neurologic lesion has changed or if spinal cord tethering has occurred, and to map the urologic treatment course.

Plain radiographs are important for the clinical evaluation for scoliosis, kyphosis, and dislocation of the hips. Evaluation of the hips should be with ultrasound before 4 to 6 months of age, as radiographs are inaccurate in this age group. Ultrasound evaluation and radiographs should be used to assess any area with pain that may represent a pathologic fracture.

### Classification

Physical examination is the key to classification, because lesion level on imaging may not accurately correlate with functional level. Deep tendon reflexes (Table 296-1) and motor movement evaluation (Table 296-2) can help identify functional level. The motor examination should focus on movements against gravity. A sensory examination, with dermatomal distribution clearly in mind, is also recommended. Often, parents are able to report accurate sensory levels when they may be difficult to elicit on examination. It is important to note any asymmetry and to document the functional level of the lesion accurately. This may allow for future timely detection of progressive neurologic deterioration.

## MANAGEMENT

Management of an individual with an NTD requires a multidisciplinary team approach. Because of the complexity of the secondary conditions associated with

**Table 296-2** Motor Movement Against Gravity and Correlative Nerve Root

MOTOR FUNCTION	NERVE ROOT
Hip flexion	L1-2
Hip adduction	L2-3
Hip abduction	L4-5
Knee extension	L3-4
Knee flexion	L5-S1
Ankle dorsiflexion, foot inversion	L4-5
Foot eversion, great toe dorsiflexion	L5-S1
Ankle plantar flexion	S1-2

NTDs, the team may include neurosurgeons, orthopedic surgeons, urologists, neurologists, physiatrists, developmental pediatricians, nurses, social workers, dietitians, and therapists, with 1 individual acting as the advocate and coordinator of the treatment program. It is also helpful for parents to have contact with a parent support group as early in the process as possible.

### Neurosurgical Management

Investigational multicenter national trials of fetal surgical closure have shown potential benefits in some children. Upon delivery, open NTDs should be immediately covered with a saline-moistened dressing to avoid rupture of the sac or drying of the exposed neural placode. To avoid placing pressure on the defect, the neonate should be maintained and examined in the prone or lateral recumbent position. Meningitic doses of broad spectrum antibiotics should be started promptly. Closure of the defect is usually performed within 72 hours after birth. The surgical repair of the defect involves removing the malformed sac, creating a barrier between the spinal canal and the exterior, and restoring the typical cerebral spinal fluid environment around the spinal cord. Operative mortality during the repair of the primary defect is extremely rare.

After the NTD is surgically closed, the ventricles often enlarge, leading to hydrocephalus; on the other hand, some neonates already have significant hydrocephalus at the time of birth. A ventricular shunt is placed in 80% to 90% of all cases. Timing of shunt placement is straightforward when there is overt clinical and radiologic evidence of hydrocephalus. The rate of shunt revision is high; approximately 40% to 50% of all children with NTDs require a shunt revision in the first year of life and approximately 10% of them every year thereafter. Once the shunt is placed, the goal becomes keeping the shunt functioning optimally. Therefore, each patient should be followed closely for signs and symptoms of shunt malfunction. An alternative to a ventricular shunt is an endoscopic third ventriculostomy, which may be appropriate in certain cases.

A potentially treatable cause of neurologic deterioration in myelomeningocele patients is spinal cord tethering. Following the initial surgical repair, the

terminal spinal cord is commonly imbedded in scar tissue. Tethered cord syndrome is a stretch-induced functional disorder of the spinal cord caused by anchoring of caudal portion of the cord by an inelastic structure. Because essentially all children with repaired myelomeningocele will have a tethered spinal cord, as demonstrated on MRI, the diagnosis of tethered cord syndrome is made on clinical grounds. Evaluation of urologic, motor, and sensory function, as well as symptoms of pain, change in gait, and orthopedic deformity should drive the diagnosis and the treatment of tethered cord syndrome. Untethering is reserved for individuals who have progressive symptoms. The release of a tethered cord may offer improvement or stabilization of neurologic function, urologic dysfunction, and orthopedic deformities. As the cord can re-tether, a multidisciplinary team discussion is important in making decisions to repeat an untethering procedure.

Although the Chiari II malformation is commonly associated with myelomeningoceles, it is only symptomatic enough to require surgical intervention in 15% to 35% of cases.

### Urologic Management

Because the bladder's nerve supply originates from the thoracic, lumbar, and sacral cord, bladder function in children with NTDs is often affected to varying degrees, though level of lesion is not explicitly predictive of bladder function. Regardless of the level of the NTD, all patients should have urinary function monitored. The priority of urologic management is to preserve kidney function and to attain bowel and bladder continence.

Only 10% to 15% of all children with myelomeningoceles are continent of urine; social continence may be achieved by the use of intermittent catheterization. Clean intermittent catheterization successfully eliminates urine from the bladder, mimicking normal voiding; this decreases urinary infection and reduces the effects of hostile bladder pressure on the kidneys. Although clean intermittent catheterization may lead to bacterial colonization of their bladder, it generally does not require antibiotic therapy unless it is symptomatic.

When poor bladder compliance or uninhibited contractions are present, medication, such as an anticholinergic agent, oxybutynin (ditropan), may be started in an attempt to improve bladder compliance and to decrease storage pressure. Urodynamic monitoring of storage pressures and leak point pressure is key to both preservation of renal function and attainment of social urinary continence. Some individuals who are unresponsive to nonsurgical management with anticholinergic medication and catheterization may benefit from operative intervention. These operative procedures are tailored to each individual, but may include vesicotomy, augmentation cystoplasty, catheterisable stoma (Mitrofanoff), slings, or artificial urinary sphincters.

### Bowel Management

Attaining and sustaining bowel continence is a complex issue for individuals with spina bifida. Fecal

incontinence can be socially isolating and, therefore, must be addressed and managed early. In thoracic level spina bifida, there is often difficulty in bearing down, while patients with sacral lesions may have difficulty achieving appropriate stool consistency.

Constipation is common and results from a multitude of factors, including diet, lack of exercise, and mobility, anticholinergic medications, and neurologic dysfunction of the bowel. It can exacerbate bladder function problems and present a risk factor for urinary tract infections. Oral medications can be used to control consistency. Bowel emptying techniques are the cornerstone of stool continence in spina bifida. Goals of a bowel program should include having soft, formed stools on a daily basis. Bowel emptying techniques include behavioral training, rectal stimulation, suppositories, and enemas. Certain patients may benefit from surgical intervention. A cecostomy or a Malone procedure, in which a conduit is created to the proximal colon, may be needed. This stoma is then used for the administration of antegrade colonic enemas.

While bowel management is often time-consuming, it can greatly increase quality of life and encourage social involvement for children with spina bifida.

### Orthopedic Management

A paramount issue for most parents of children with spinal NTDs is the prognosis of ambulation. In the absence of severe developmental delay and hypotonia, ambulation is highly dependent on sensorimotor functional level.

Strong hip flexors, adductors, and quadriceps are needed to ambulate. Independent mobility is likely for almost all cases of low lumbar and sacral lesions. For lesions above L2, independent mobility is unlikely and parents should anticipate wheelchair use. As some children age, their ability to ambulate often declines because of the increased physical effort of walking required by increasing weight and orthopedic deformity. Consequently, a wheelchair may become a more efficient alternative for adolescents and adults.

It is important that an orthopedist be involved in the care of patients with myelomeningocele, as paralysis, muscle imbalance, and spasticity produce orthopedic deformities that often require surgical correction. Spinal deformities in myelomeningocele, such as scoliosis and kyphosis, are exceedingly common. Hip dislocations also frequently occur, but do not always require treatment. Severe foot deformities are seen in up to 80% of children.

For optimal motor function, early involvement of a physical therapist is critical. Range of motion exercises are essential at any age. Goals of physical therapy should include normalization of experiences, improvement of posture for sitting or standing, management of orthotics, and prevention of skin breakdown. Orthotics are commonly used to prevent contractures and promote development of an individual's mobility. They also aid in minimizing energy expenditure to maintain mobility. If feasible, a standing program should be instituted at an early age. Specialized equipment, such as walkers, braces, standers, and parapodiums, may be needed to provide support and promote mobility.

### Developmental and Cognitive Issues

The range of developmental outcomes in individuals with NTDs is extensive. In general, cognitive function is often higher for those with lower lesions and for children who do not experience CNS infections (ventriculitis or meningitis). For individuals without associated hydrocephalus, cognitive function is commensurate with same-age peers.

Most children (80%) with myelomeningocele have intelligence within the normal range, yet they often have specific learning disabilities. Nonverbal learning disorders are associated with hydrocephalus and found more often in children with myelomeningocele with stronger language skills and weaker visual-perceptual and visual-motor skills. Corresponding academic skills include stronger reading decoding and spelling skills and weaker mathematic and reading comprehension skills. In addition, they often have difficulty with attention and executive function, with an increased risk of attention-deficit/hyperactivity disorder. Routine neuropsychologic and psychoeducational evaluations for children with spina bifida ensure that all learning issues are identified.

Referral for an early intervention program and physical therapy are essential during the neonatal period. Given the high incidence of visual-motor and visual-perceptual difficulties associated with hydrocephalus, occupational therapy is also often needed. As children access school services, families should participate in the development of an Individualized Education Plan with school personnel. For adolescents with an NTD receiving special education services, transition plans should begin by age 14 years to specifically address transition to vocational and occupational domains and to assist families in navigating the transition from childhood to adulthood.

It is also important for physicians to remember that families who cope with an NTD are faced with challenges that are very different than those faced by families raising typically developing children. Stressors include the need for continuous interaction with medical care agencies and an increased level of financial stress. Parenting quality and care patterns have an important effect on developmental outcomes in children; specifically, high-quality parental care is linked to higher cognitive abilities and social competence. As family members are likely the main source of support for both physical and psychologic well-being for individuals with spina bifida, physicians should encourage healthy family relationships to support optimal family functioning. Family support groups are often helpful and should be encouraged.

### Dermatologic Issues

Because of impaired sensation caused by spinal cord dysfunction, patients with spina bifida have an increased rate of skin breakdown and pressure sores. Intervention for early signs of inflammation is imperative. Measures to protect insensate skin, such as properly fitted orthotics and shoes, wheelchair push-ups, and time out of the wheelchair, are paramount. As children mature, they should be taught how to check their own skin daily for evidence of pressure sores.

### Latex Allergy

Allergies to latex are more common in this population; reactions can vary from mild to anaphylaxis. Beginning at birth, latex precautions should be in place for patients with myelomeningocele. Latex avoidance in children with spina bifida has been demonstrated to prevent latex sensitization and latex allergy.

### ONGOING CARE

#### Prognosis

There has been a tendency for prenatal counseling to be unduly negative, failing to recognize the heterogeneity of these conditions and the effect of contemporary postnatal medical and surgical management. Prognosis for all NTDs is largely dictated by anatomical site, extent of CNS tissue involvement, and the presence of coexisting conditions. Long-term prognosis for survival is less optimistic if there is an associated syndrome, brain tissue herniation, or repeated CNS infections.

In children with myelomeningocele, prognosis for survival can be improved if shunts function optimally and if kidney function is preserved. In older patients these are the most common, and potentially preventable, causes of death.

#### Prevention

The periconceptional use of daily supplements containing 0.4 mg of folic acid has been shown to prevent 40% to 80% of cases of spina bifida and anencephaly. Counseling provided to women with a previous NTD-affected pregnancy and supplementation with 4.0 mg of folic acid have also been demonstrated to substantially reduce the risk of recurrent NTDs. In addition, countries that have implemented mandatory folic acid food fortification programs have succeeded in significantly reducing the prevalence of NTDs.

### WHEN TO REFER

- Evidence of raised intracranial pressure, such as vomiting or changes in mental status.
- Symptoms of spinal cord tethering.
- Recurrent urinary tract infections.
- Renal calculi or impairment.
- All children 0 to 3 years of age should be referred to an early intervention program.
- Children entering school should be referred to their school district's preschool program to have a formal evaluation of cognitive functioning.
- All patients should be referred to a multidisciplinary clinic where specialists in development, genetics, neurosurgery, nursing, nutrition, orthopedics, orthotics, social work, therapy (occupation and physical), and urology participate or are available.

## Chapter 297 NEUROCUTANEOUS SYNDROMES

Dwayne E. Dove, MD; Michael L. Smith, MD

The neurocutaneous disorders consist of a heterogeneous group of conditions in which abnormalities of skin and nervous system predominate. Classically, neurofibromatosis, tuberous sclerosis, and von Hippel-Lindau disease are considered the prototypical neurocutaneous conditions. However, several other genetic or developmental anomaly syndromes share the phenotypic association of cutaneous and neurologic abnormalities, such as Sturge-Weber syndrome, ataxia-telangiectasia, incontinentia pigmenti, hypomelanosis of Ito, and the epidermal nevus syndromes. In addition, many genetic disorders with neurodevelopmental features may exhibit skin lesions, but these myriad conditions are beyond the scope of this chapter. The current discussion focuses on neurofibromatosis, tuberous sclerosis, Sturge-Weber syndrome, von Hippel-Lindau disease, and ataxia-telangiectasia.

NEUROFIBROMATOSIS

Definition

Neurofibromatosis is classically divided into type 1 (NF1) and type 2 (NF2), although these are different conditions with only minimal overlap. Both are autosomal; dominant disorders with high penetrance but variable phenotypic expression. NF1 is more common, occurring in approximately 1 in 3,500, and commonly presents in childhood. The incidence of NF2 is approximately 1 in 25,000, and it usually manifests in the late teens and 20s. No race or gender predilection has been found. Approximately one-half of the cases with each condition represent new mutations. Further recognition of variants has led to expanded classification into 8 subtypes (Table 297-1).

Neurofibromatosis Type 1

NF1, or von Recklinghausen disease, is a complex disorder with neurologic, cutaneous, skeletal, vascular, and endocrinologic abnormalities. A loss-of-function mutation in the neurofibromin tumor suppressor gene is thought to be responsible for most of the clinical features. The characteristic lesion is the neurofibroma,

a proliferation of Schwann cells and fibroblasts, from which the condition derives its name. Neurofibromas are benign tumors that appear in late childhood, grow in response to hormonal changes, proliferate with age, and may compromise local function by mass effect. Small neurofibromas appear as pink to flesh-colored to brown papules with a soft, spongy texture (Figure 297-1). On occasion, gentle downward pressure can cause these lesions to sink through the underlying dermis, creating a dimple (Figure 297-2). Size and number vary greatly. A slight predilection for trunk involvement seems to exist, although neurofibromas can occur anywhere on the body.

A variant of neurofibroma, the plexiform type, can be large and can cause considerable disfigurement. Plexiform neurofibromas (Figure 297-3) are highly variable masses that may have surface hyperpigmentation or may remain flesh colored. Overlying skin may be somewhat thickened and may exhibit increased hair growth. Plexiform neurofibromas often produce soft tissue masses, sometimes feeling soft and spongy in texture, and other times feeling similar to a bag of rope. Plexiform lesions are seen in approximately 50% of patients with NF1.

Table 297-1      Neurofibromatosis Spectrum		
FORMER CLASSIFICATION	CURRENT TERMINOLOGY	CHARACTERISTICS
Type 1	NF1	See text
Type 2	NF2	See text
Type 3 (variant), type 4 (atypical)		Autosomal dominant; not used clinically
Type 5 (segmental)	Segmental NF	Skin lesions all on 1 body segment (eg, leg); somatic mosaicism
Type 6 (CALMs)	Familial CALMs	Only has CALM; must have 2 generations to diagnose
Type 7 (late onset)	Schwannomatosis	Symptoms manifest in the 20s; multiple schwannomas; no vestibular or intradermal schwannomas
Type 8 (not otherwise specified) not used clinically		

CALM, café-au-lait macules; NF, neurofibromatosis.  
Derived from Boyd KP, Korf BR, Theos A. Neurofibromatosis type 1. *J Am Acad Dermatol.* 2009;61:1–14.

Figure 297-1 Cutaneous neurofibromas in neurofibromatosis type 1.

The earliest features are often café-au-lait macules (CALMs), which are tan, oval macules with smooth margins and no surface texture change (Figure 297-4). They remain flat and do not exhibit increased hair growth. They may vary in size and shape, and they may increase in number and size with age.

Axillary or inguinal freckling is seen in almost 90% of NF1 patients, usually developing between 3 and 5 years of age.

**Figure 297-2** Neurofibroma dimpling through underlying dermis.

**Figure 297-3** Plexiform neurofibroma on a breast.

**Figure 297-4** Multiple café-au-lait macules on an infant, with coincidental gray Mongolian spot.

### Diagnosis

NF1 is a highly variable condition, with age-specific expression of its clinical features. Although minor evidence occurs often in infancy with only CALMs, NF1 cannot be diagnosed clinically until 2 or more of the major diagnostic criteria are met (Box 297-1). This feature is particularly important in view of the many other disorders in which CALMs are a presenting feature (Table 297-2).

### Evaluation

The evaluation of patients for possible NF1 depends on age; many of the features develop over time. For example, CALMs are present at birth but will increase in size and number for the first 5 to 7 years. Bowing of the long bones (especially tibia) and cutaneous plexiform neurofibromas typically are visible within the first year of life, whereas axillary (Figure 297-5) and inguinal freckling, optic gliomas, and scoliosis may not be apparent until age 7 years. Cutaneous neurofibromas and iris Lisch nodules usually appear during or after the teenage years.

**HISTORY.** Relevant history should include questions about developmental milestones, including language, social skills, and learning. Emotional and behavioral functioning also needs to be explored, particularly issues regarding self-esteem. Family history is of paramount importance in the initial evaluation of a child with only CALMs because the presence of NF1 in a first-degree relative secures the diagnosis.

**PHYSICAL EXAMINATION.** Initial examination of any child for NF1 should start with a thorough skin survey for CALMs. Six or more CALMs should raise the index of suspicion. Thorough examination of the entire skin surface should also reveal the presence of plexiform neurofibromas. Plexiform neurofibromas may be present at birth or may develop in the first few years of life. Careful attention should also be paid to the long bones of the lower leg because congenital

### BOX 297-1 Diagnostic Criteria for Neurofibromatosis Type 1

NF1 is present when a patient has 2 or more of the following:

- Six or more café-au-lait spots larger than 5 mm in pre-pubertal child and 15 mm after puberty
- Axillary or inguinal freckling
- At least 2 neurofibromas of any type or at least 1 plexiform neurofibroma
- Optic pathway glioma
- At least 2 Lisch nodules of the iris
- Characteristic bony lesion (sphenoid wing dysplasia, or thinning of the cortex of long bones—with or without pseudoarthrosis)
- First-degree relative with NF1

NF1, neurofibromatosis type 1.

Adapted from Yohay K. Neurofibromatosis types 1 and 2. *Neurologist*. 2006;12:86–93; and Tongsgard JH. Clinical manifestations and management of neurofibromatosis type 1. *Semin Pediatr Neurol*. 2006;13:2–7.

**Table 297-2** Differential Diagnosis of Multiple Café-au-Lait Macules

CONDITION	OTHER CLINICAL FEATURES	COMMENT
Normal	—	Up to 25% of normal individuals may have 1–3 CALMs. Up to 40% of people with >6 CALMs and no other symptoms never progress to NF1.
NF1	Axillary freckling, cutaneous NFs, plexiform NFs, Lisch nodules, optic glioma, bony abnormalities, positive family history	Present in 95% of patients with NF1; must have >6 CALMs (>5 mm before puberty; >15 mm after puberty)
NF1-like syndrome	Axillary freckling, multiple CALMs, macrocephaly; no neurofibromas or Lisch nodules	Also called <i>Legius syndrome</i> ; caused by <i>SPRED1</i> mutation; may have learning disability
Hereditary nonpolyposis colon cancer syndrome	Axillary freckling, multiple CALMs, cutaneous neurofibromas; colon cancer at early age	Homozygous form, usually with consanguinity
Watson syndrome	Pulmonic stenosis, ID, axillary freckling	Axillary freckling only in NF1 and Watson syndrome type 1
McCune-Albright syndrome	Polyostotic fibrous bony dysplasia, precocious puberty, hyperthyroid, Cushing syndrome	Usually large-segment CALM with irregular border ( <i>coast of Maine</i> )
Russell-Silver syndrome	Short stature, skeletal asymmetry, abnormal pubertal development	Café-au-lait spots and small achromic macules have been reported, but are not constant features.
Bloom syndrome	Malar facial erythema and telangiectasia; photosensitivity; long, narrow face with prominent nose; short stature; hypogonadism; malignancy risk	Facial photosensitivity with multiple CALMs triggers evaluation.
Tuberous sclerosis	Hypopigmented macules, facial and periungual angiofibromas, seizures, ID, renal and cardiac hamartomas	Hypopigmented macules more common; mixture very concerning for tuberous sclerosis complex.
Noonan syndrome	Hypertelorism, webbed neck, short stature, leg lymphedema, pulmonic stenosis, hypogonadism	CALMs may be seen in 15% of patients with Noonan syndrome.

CALM, café au lait macule; ID, intellectual disability; NF, neurofibromatosis; NF1, neurofibromatosis type 1.

Adapted from Krowchuk DP, Mancini AJ, eds. *Pediatric Dermatology: A Quick Reference Guide*. Elk Grove Village, IL: American Academy of Pediatrics; 2007; and Spitz JL. *Genodermatoses: A Full-Color Clinical Guide to Genetic Skin Disorders*. New York, NY: Williams & Wilkins; 1996.

**Figure 297-5** Axillary freckling in neurofibromatosis type 1.

tibial dysplasia is an early finding in up to 5% of children with NF1. Any curvature or nodularity of the tibia is worrisome, as is any length discrepancy. Head circumference should be monitored at each visit because approximately 50% of children with NF1 have macrocephaly. Thorough developmental evaluation

should be undertaken at each visit and repeated at regular intervals, with attention to language, visual motor skills, and learning in toddlers and preschool-aged children.

Examination of the back for evidence of scoliosis should start by age 2 years because scoliosis appears at an earlier age in NF1, and a severe dystrophic form of kyphoscoliosis can appear between 3 and 5 years of age. Regular blood pressure assessment should also begin by age 2 years. Ophthalmologic evaluation should be obtained annually to age 10 years to assess for the presence of optic pathway glioma. These grade 1 pilocytic astrocytomas, which are present in approximately 15% of children with NF1 younger than 10 years, may produce proptosis, strabismus, papilledema, or vision loss. If the optic chiasm is involved, then hypothalamic extension can produce an endocrinopathy, resulting in precocious or delayed puberty. The development of precocious puberty should prompt evaluation for an optic glioma. Similarly, any rapid increase in linear growth should prompt an investigation for optic pathway glioma with growth hormone excess. Other ocular findings may include congenital ptosis or orbital asymmetry (the latter the result of sphenoid wing dysplasia).

School-aged children should be assessed for limb asymmetry, long bone bowing, scoliosis, and cutaneous neurofibromas. School performance should be addressed, with particular attention to learning disabilities, attention-deficit/hyperactivity disorder (ADHD), executive dysfunction, self-esteem, and socialization.

Teens should be assessed for limb asymmetry, scoliosis, neurofibromas, and hypertension. Ophthalmologic evaluation, including slit-lamp examination, should be obtained to look for iris hamartomas (Lisch nodules). These tan to brown papules usually appear in the teen years, but they have minimal effect other than support of diagnosis. Any complaint of pain, particularly pain associated with focal neurologic deficit or arising from a plexiform tumor, should be thoroughly evaluated by examination and imaging studies. School performance, socialization, and self-esteem issues should be addressed as well.

**LABORATORY EVALUATION.** Routine laboratory testing is unnecessary in NF1 if the diagnosis is firmly established. However, if reason exists to test for gene mutations (in cases of uncertain diagnosis, a child with only CALMs or only 1 criterion), then a complementary series of analyses—including premature truncation test, heteroduplex analysis, and fluorescent in situ hybridization assay—is available clinically. This tiered analysis provides a sensitivity of 95%. Genetic testing may have limited clinical value, with lack of genotype-phenotype correlation except in 2 situations: complete loss of the NF1 gene, which portends more severe disease with severe cognitive impairment, large tumor burden, and higher risk for malignant peripheral nerve sheath tumors; and a known small deletion in exon 17, which confers a milder phenotype without cutaneous neurofibromas.

**IMAGING STUDIES.** Imaging in NF1 should be directed toward evaluation of symptoms. Routine neuroimaging is generally not undertaken. However, head magnetic resonance imaging (MRI) is indicated for evaluation of focal neurologic changes, new-onset seizures, severe headaches, vision changes, proptosis, short stature, rapid change in head circumference, plexiform lesions, severe cognitive deficits, and precocious or delayed puberty. Any evidence of scoliosis or any long bone anomaly should merit plain-film radiography. Scoliosis may also require MRI or computed tomography (CT) to define the extent and help map surgical intervention. MRI is also useful to assess for radiculopathy because neurofibromas have a propensity to develop along or within the spine, often impinging on nerve roots. The development of pain, or any focal neurologic deficit, also warrants a thorough evaluation, including MRI. This evaluation is particularly important if pain develops in a plexiform neurofibroma because pain may herald malignant change. Although MRI is the mainstay of evaluation of plexiform neurofibromas, positron emission tomography (PET) may be of more value in distinguishing benign from malignant lesions. Cranial MRI is indicated to evaluate for possible optic pathway glioma after symptoms have developed. Routine imaging before symptom onset is not indicated. After optic gliomas are diagnosed, MRI should be obtained every 2 years and with any symptom change to age 10 years.

Imaging is also useful in evaluation of cerebrovascular disease and renal artery stenosis.

One unusual finding in NF1 is the presence of unidentified bright objects on T2-weighted sequences of cranial MRI. These lesions, which are present in 60% to 90% of children but only in approximately 30% of adults, are of uncertain significance. Controversial evidence suggests that some learning disabilities seem to correlate with the presence and specific locations of unidentified bright objects.

### Management

Management and health supervision of NF1 should focus on the many organ systems involved, given the wide variability of expression. As a rule, genetic counseling should be provided for all NF1 families because affected individuals have a 50% chance of transmission with each pregnancy.

Neurofibromas present unique management issues of their own. Smaller lesions may become painful or may interfere with activities as a result of location. Plexiform lesions can be disfiguring, especially when they are present on the head or neck. The presence of numerous or large lesions may exert a profound effect on self-esteem and socialization. Surgical excision may be necessary for problematic tumors. Sudden development of pain or focal neurologic deficit in plexiform tumors may represent malignant degeneration. Malignant peripheral nerve sheath tumors (formerly called neurofibrosarcomas) develop in 5% to 13% of patients with NF1, with devastating effect. These aggressive tumors typically arise in the 20s and 30s, are often multicentric, and metastasize quickly. Despite aggressive therapy, they are usually fatal within a year. Other malignant tumors are seen in NF1, with an overall incidence 3% higher than the general population. These tumors include leukemia (especially juvenile myelomonocytic leukemia), rhabdomyosarcoma, pheochromocytoma, gastrointestinal stromal tumors, and carcinoid. The last 3 tumors are predominantly adult-onset tumors.

Optic pathway gliomas develop in 15% to 20% of patients with NF1 at a mean age of 4.2 years. Careful ophthalmologic monitoring for vision change, afferent pupillary defect, or change in funduscopic examination findings should begin in the first year of life and continue annually to age 10 years. Progression of the gliomas beyond age 10 years is rare. Other ocular findings may include congenital ptosis, congenital glaucoma, and pulsating exophthalmos. If optic pathway glioma is present, MRI evaluation should be repeated every 2 years until age 10 years in addition to annual ophthalmologic examinations. Precocious or delayed puberty may be a later clinical sign of optic glioma extending from the chiasm into the hypothalamus and should prompt reevaluation and MRI.

Hormonal surges may affect NF1 and should be discussed with preteens and teens. Oral contraceptives, puberty, and pregnancy are likely to cause increases in both size and number of neurofibromas.

Identification of neurologic and neurodevelopmental issues is of paramount importance in the management of patients with NF1. Headaches occur in 20% of patients;

these are usually migraines that respond well to standard therapy such as amitriptyline or topiramate. Seizures occur in 4% to 10% of patients with NF1 and may include partial or generalized variants or even infantile spasms. Management should be directed toward the specific seizure type (see Chapter 327, Seizure Disorders). Hearing loss, usually unilateral, occurs in approximately 10% of patients with NF1. Learning disabilities are observed in 35% to 65% of children with NF1 compared with less than 20% of the general population. A slight downward shift often occurs in IQ compared with age-matched controls, but the incidence of intellectual disability is only 4% to 8% (approximately twice that of the general population). Learning disabilities are variable, but may include math and reading comprehension problems. In addition, visual perception deficits and delays in both gross- and fine-motor skills are common. Speech and language delays are seen in approximately one-half of these children. ADHD is also common, occurring in approximately one-half of children with NF1. A variety of behavioral problems are seen with increased frequency in NF1 and may include anxiety, depression, social problems, aggression, and unusual behaviors. These issues seem to correlate more with the comorbid diagnosis of ADHD than with academic achievement. Autism spectrum disorders may be seen in up to 14% of children with NF1. Vascular disease is more common in patients with NF1, which may include congenital heart defects, hypertension, occlusive arterial disease, aneurysms, or arteriovenous fistulas. Hypertension in young children may result from renal artery stenosis (1% of patients with NF1). Hypertension in adults may be primary or associated with pheochromocytoma (rarely renal artery stenosis in adults). Workup should include renal angiography in children and urine catecholamine levels in adults.

Bone abnormalities are common in NF1, ranging from skeletal dysplasia to nonossifying fibroma to short stature to kyphoscoliosis. Long bone dysplasia (especially tibia) may be seen during the first year of life and may present as bowing or, rarely, pseudoarthrosis (nodule at the site of a healing pathologic fracture). Pseudoarthrosis occurs in only 3% of children with NF1. Nonossifying fibromas occur in late childhood to the teen years and may lead to pathologic fractures, particularly in the femur, tibia, and humerus. Scoliosis is seen in 10% of children with NF1 and may develop earlier than in the general population. An aggressive dystrophic form may develop between 3 and 7 years of age.

Life expectancy is approximately 10 to 15 years shorter in NF1 compared with the general population, with malignancy and vascular disease as the leading causes of death.

### Neurofibromatosis Type 2

NF2 is a tumor syndrome defined by the presence of bilateral vestibular schwannomas with associated hearing loss. The NF2 gene encodes merlin, or schwannomin, a cytoskeletal protein that may have regulatory and signaling functions. The precise mechanism of tumor formation is uncertain. NF2 is 100% penetrant—patients with the mutation have the disease. However, expressivity is highly variable, with

variable size, number, and location of tumors. In addition to the characteristic vestibular schwannomas that lead to progressive deterioration of hearing, patients with NF2 may develop intracranial or spinal meningiomas; ependymomas; astrocytomas; neurofibromas; schwannomas of the cranial, spinal, and peripheral nerves; and cutaneous schwannomas (the latter with minimal clinical effect). Meningiomas are seen in about 50% of NF2 patients, although the lifetime risk may be as high as 75%. Meningiomas may be the presenting feature, particularly in childhood. Ependymomas and astrocytomas are seen in up to 33% of patients. Peripheral schwannomas may arise from any nerve and may produce pain or sensory or motor dysfunction. Spinal intramedullary tumors, often multiple, are usually ependymomas. Patients with NF2 may also develop peripheral neuropathy that is not related to tumor growth. Seizure disorders are uncommon in NF2. Similarly, cognitive impairment is not a feature of NF2. Ocular findings in NF2 include juvenile posterior subcapsular lens opacities, retinal hamartomas, epiretinal membrane, and cortical wedge opacities. The average age at onset of symptoms is approximately 20 years, with average age at diagnosis of 28 years. Almost all patients develop bilateral vestibular schwannomas by age 30 years. However, 18% of patients show symptoms before age 15 years. NF2 is often underrecognized in children, with ocular or cutaneous findings, or meningioma, presenting in the first few years of life. An increasingly recognized early presentation is mononeuropathy in children, often with persistent facial palsy, squint, or hand or foot drop.

### Evaluation

**HISTORY.** Relevant history for NF2 should include any vision or hearing changes, tinnitus, vertigo, gait disturbances, decreased facial sensation, facial weakness or twitching, hoarseness, dysphagia, or headaches. Family history of NF2 is crucial for diagnosis (Box 297-2).

**PHYSICAL EXAMINATION.** Examination of a patient for NF2 should focus on vision, hearing, and cranial and peripheral nerve function. Younger patients often have headache, tinnitus, cranial nerve symptoms, or skin or spinal tumors before the onset of hearing loss. Eye examination should assess the presence of lens opacities. Cranial nerve examination should specifically address the trigeminal, facial, and auditory nerves. Neurologic examination should assess balance, gait, and deep tendon reflexes. At the skin examination, the physician should note the presence of neurofibromas, CALMs, or cutaneous schwannomas. Cutaneous schwannomas are present in approximately one-half of patients with NF2; they may be subcutaneous nodules or plaques with thickened texture and occasional hair growth, or surface pink to flesh-colored papules (Figure 297-6).

**LABORATORY EVALUATION.** Laboratory testing for possible NF2 should always include formal audiologic testing for sensorineural hearing loss, including a brainstem auditory evoked response. After the diagnosis of NF2 is established, audiometry should be repeated every 6 to 12 months. Molecular genetic testing for the mutations is available on a clinical basis

### BOX 297-2 Diagnostic Criteria for Neurofibromatosis Type 2

#### DEFINITE NF2

- Bilateral vestibular schwannomas
- or
- First-degree relative with NF2
- plus
- Unilateral vestibular schwannomas
- or
- Any 2 of the following: meningioma, schwannoma, glioma, neurofibroma, juvenile posterior subcapsular cataract

#### PROBABLE NF2

- Unilateral vestibular schwannoma
- plus
- Any 2 of the following: meningioma, schwannoma, glioma, neurofibroma, juvenile posterior subcapsular cataract
- or
- Multiple meningiomas
- plus
- Unilateral vestibular schwannoma
- or
- Any 2 of the following: schwannoma, glioma, neurofibroma, juvenile posterior subcapsular cataract

NF2, neurofibromatosis type 2.

**Figure 297-6** Multiple schwannomas in neurofibromatosis type 2.

and should be used for relatives at risk. This will allow appropriate long-term screening if needed and might prevent unnecessary expensive testing.

**IMAGING STUDIES.** The most useful imaging modality for assessment of vestibular schwannomas is gadolinium-enhanced MRI with thin cuts through the internal auditory canals. Routine screening MRI of the brain is required for any patient with unilateral vestibular schwannoma, multiple intracranial or spinal

tumors, or a first-degree relative with NF2, or for a child with meningioma. As with audiometric testing, any child at risk for NF2 should have a screening brain MRI annually beginning at age 7 years. Spinal MRI should be considered if any symptoms or neurologic deficits are noted.

#### Management

The most important aspect of management in NF2 is early diagnosis so that surgery to preserve the hearing can be performed. Advanced tumors may prevent the preservation of hearing, leading to the need for either cochlear or auditory brainstem implants or possibly leading to complete deafness. At present, cochlear implants seem to be better than auditory brainstem implants for patients with NF2. After a diagnosis of NF2 is made, the child should be evaluated by ophthalmologic, otolaryngologic, audiologic, and imaging studies. Screening examinations, audiometry, and imaging should then be repeated at least annually starting at age 7 years. Children of a parent with NF2 should have annual ophthalmologic examinations starting in infancy and neurologic and audiometric examinations annually from age 7 years. Most patients with NF2 should be encouraged to learn sign language to prepare for possible future complete hearing loss. Patients with vestibular tumors should also be counseled that problems with balance and underwater disorientation pose drowning risk. Management of the tumors is still primarily surgical. Radiation therapy should be avoided, particularly in children, because of the risk for inducing or accelerating tumor growth.

The prognosis of NF2 is poor, despite the benign nature of the tumors. Location of the tumors often increases morbidity and mortality, with average age at death of 36 years. Survival for patients presenting at age 30 in the past 20 to 30 years was 15 years from diagnosis. Early detection and removal of tumors shows promise for prolonged survival.

#### WHEN TO REFER

##### NF1

- Pediatric ophthalmologic evaluation beginning in the first year
- Neurologic evaluation if seizures are difficult to manage
- Neurodevelopmental testing if evidence of learning disability, ADHD, and speech delay
- Surgical referral for symptomatic neurofibromas, renovascular hypertension

##### NF2

- Hearing loss or tinnitus should prompt referral for audiologic evaluation.
- Headache, gait, or balance concerns should prompt referral to neurology.

#### WHEN TO ADMIT

- Sudden neurologic decline or uncontrollable seizures

## TUBEROUS SCLEROSIS COMPLEX

### Definitions

Tuberous sclerosis complex (TSC), or Bourneville disease, is an autosomal-dominant multisystem disorder characterized by perturbed cellular growth and differentiation in the brain, heart, kidneys, skin, eyes, and other tissues. Although a dominant disorder, approximately 70% of cases arise as spontaneous new mutations. The prevalence of TSC is approximately 1 in 6,000. TSC results from mutations in 1 of 2 genes: *TSC1*, which encodes hamartin, or *TSC2*, which encodes tuberin. Hamartin and tuberin bind together as a heterodimeric protein involved in regulation of cell growth. The intact protein suppresses the protranslational effects of mammalian target of rapamycin. When either hamartin or tuberin is defective, mammalian target of rapamycin starts uncontrolled promotion of protein synthesis and cell growth, leading to tumor formation. Approximately 45% of cases with known mutations are caused by *TSC1*/hamartin mutations, and 55% are caused by *TSC2*/tuberin mutations. Fifteen percent to 20% of patients with TSC have no mutation identified. Determination of the type of mutation (see Laboratory Evaluation) is important for prognosis and may allow more selective emphasis on specific management strategy by mutation type. Patients with *TSC2* mutations are more likely to present with infantile spasms, developmental delay, and angiofibromas and often have more severe disease. Patients with *TSC1* mutations more often present with family history or hypomelanotic macules and may have less severe disease. Patients with no identified mutation are more likely to present with renal angiomyolipomas. Mutations of *TSC1* are more common in familial cases and seem to result in less severe disease.

The classic triad of seizures, intellectual disability, and facial angiofibromas is far from a complete picture of this complex, but highly variable, condition. In fact, only 29% of TSC patients have the complete Vogt triad, and 6% lack all 3 symptoms. Seizures and facial lesions do indeed occur frequently, but intellectual function is often normal or only slightly impaired. Approximately one-half of patients with TSC have normal intelligence, whereas approximately 30% have profound intellectual disability. The hallmark of TSC is the development of hamartomas in the various organ systems involved. An international consensus conference in 1998 developed revised diagnostic criteria for TSC based on newer understanding of the disease and its underlying pathophysiologic features. A summary of these criteria is found in Box 297-3. An important point to note is that TSC has no pathognomonic feature. Because an individual feature may occur as an isolated finding, the primary care physician must consider the diagnosis of TSC only if more than 1 organ system is involved or if different lesion types occur in a single system.

### Central Nervous System Manifestations

Central nervous system (CNS) disease is the most common and often most disabling aspect of TSC. The neurologic features of TSC include seizures, cognitive disability, and behavioral disturbances. Seizures occur in 80% to 90% of patients with TSC.

### BOX 297-3 Diagnostic Criteria for Tuberous Sclerosis Complex

#### MAJOR CRITERIA

- Facial angiofibroma or forehead plaque
- Ungual or subungual fibroma
- More than 3 hypomelanotic macules
- Connective tissue nevus (Shagreen patch)
- Cortical tuber<sup>a</sup>
- Subependymal nodule
- Subependymal giant cell astrocytoma
- Multiple retinal hamartomas
- Cardiac rhabdomyoma
- Renal angiomyolipoma
- Lymphangiomyomatosis

#### MINOR CRITERIA

- Dental enamel pits
- Hamartomatous rectal polyps
- Bone cysts (radiographic evidence sufficient)
- Cerebral white matter migration lines<sup>a</sup>
- Gingival fibromas
- Retinal achromic patch
- Nonrenal hamartomas
- Multiple renal cysts
- Confetti skin lesions

#### DIAGNOSIS

- Definitive: 2 major or 1 major and 2 minor criteria
- Probable: 1 major criterion plus 1 minor criterion
- Possible: 1 major or 2 or more minor criteria

<sup>a</sup>When cortical dysplasia (tuber) and cerebral white matter migration tracks are both present, they count as 1 criterion rather than 2 criteria.

Adapted from Rosser T, Panigrahy A, McClintock W. The diverse clinical manifestations of tuberous sclerosis complex: a review. *Semin Pediatr Neurol.* 2006;13:27–36; Roach ES, Sparagana SP. Diagnosis of tuberous sclerosis complex. *J Child Neurol.* 2004;19:643–649; and Crino PB, Nathanson KL, Henske EP. The tuberous sclerosis complex. *N Engl J Med.* 2006; 355:1345–1356.

All types of seizures except classic absence seizures have been reported in TSC. One of the more common forms is infantile spasms, seen in approximately one-third of infants with TSC. Infantile spasms are the presenting feature in 70% of infants with TSC. A thorough description of the clinical and electroencephalographic findings in infantile spasms is found in Chapter 327, Seizure Disorders. Children with infantile spasms are likely to have intellectual disability.

Seizure onset and severity are also closely associated with severity of cognitive impairment. Early onset of seizures or infantile spasms is associated with poor cognitive outcome. Although most patients with TSC and cognitive disability have epilepsy, many patients with TSC and seizures have normal intellect. However, children with infantile spasms are often cognitively impaired, corresponding to increased cortical hamartoma (tuber) burden in both circumstances. Furthermore, the presence of at least 7 cortical tubers on MRI confers a 5-fold increase in risk for moderate to profound

cognitive impairment, although a few patients with multiple tubers and normal intellect have been reported.

Autism spectrum disorder is also common in TSC, with prevalence estimates ranging from 17% to 68%. Autism spectrum disorder is much more common in children with intellectual disability in TSC (>60%) than among children with TSC and normal cognitive function (6%). Among children with autism spectrum disorder, TSC is found in up to 4%. Almost all children with autism spectrum disorder and TSC have epilepsy. Patients with autism and TSC do not exhibit the male preponderance seen in autism without TSC. Similarly, among children with autism and seizures, TSC is the underlying genetic condition in 14%.

A variety of behavioral abnormalities may be seen in children with TSC, including severe temper tantrums, restlessness, impulsivity, attention deficit with hyperactivity, self-injury, anxiety, and depression. Among children with TSC and a history of infantile spasms and autism, 69% exhibit behaviors disruptive to the family by age 5 years. Anxiety disorder is seen in up to 59%, and depression in 35%, of adults with TSC.

Learning disabilities have been noted frequently in TSC, although no systematic studies are available to date.

The neuropathologic findings responsible for many of the symptoms of TSC include tubers, subependymal nodules, and subependymal giant cell astrocytomas. The cortical tubers are nodular areas of gray and white matter dysplasia, often seen on the apex of a gyrus. Tubers are present in more than 95% of patients with TSC. Tubers have been noted as early as 20 weeks' gestation and are known to persist throughout life. No risk for malignant degeneration exists. Large numbers of tubers are associated with worse overall prognosis (infantile spasms, cognitive impairment, and difficult seizure control). The tubers also function as epileptogenic foci. Subependymal nodules are present in up to 80% of patients with TSC. They arise from the lateral and third ventricle walls and often protrude into the lumen. They can be present before birth and may sometimes be noted on imaging studies during infancy. The presence and number of subependymal nodules do not seem to correlate with severity of neurologic symptoms, in contrast to tubers. Subependymal giant cell astrocytomas, on the other hand, may be symptomatic. They occur in up to 14% of patients with TSC and seem to arise from subependymal nodules. They continue to grow during childhood and may produce focal neurologic deficits or obstructive hydrocephalus.

### Cutaneous Manifestations

Skin findings are the most consistent features of TSC. Hypomelanotic macules (formerly known as *ash leaf spots*) are found in more than 90% of patients with TSC and may be present at birth (Figure 297-7). They are often the earliest sign of TSC. In light-skinned individuals, they may be visible only with a Wood's lamp. They are usually larger than 1 cm and have a characteristic leaf shape—oval with one blunt end and one pointed end. At least 3 lesions must be visible for diagnostic significance. Hypomelanotic macules are

**Figure 297-7** Facial angiofibromas and hypomelanotic macules in tuberous sclerosis complex.

seen most commonly on the trunk, but they may occur anywhere. Fine, stippled hypopigmentation on the extremities is known as *confetti lesions*. When hypomelanotic macules occur on hair-bearing surfaces, associated poliosis (white hair) may be found.

Facial angiofibromas (formerly known as *adenoma sebaceum*) are noted in 70% to 75% of individuals with TSC. These small, discrete, shiny pink to reddish papules develop by approximately age 5 years, but they increase in number and size into the teen or early adult years (see Figure 297-7). Although they are initially distributed over the malar areas, they often spread to chin and nasolabial folds during puberty. Forehead plaques are flesh-colored to erythematous fibrotic plaques on the forehead or frontal scalp in approximately 19% of patients with TSC. They appear later than angiofibromas.

Shagreen patches are connective tissue nevi seen in 20% to 50% of patients with TSC. These patches are flesh-colored, slightly raised, irregularly shaped plaques with prominent follicles and cobblestone texture and are seen most often on the lower back (Figure 297-8). They are usually noted in later childhood.

Ungual and subungual fibromas are firm flesh-colored to red papules that develop beside or beneath the nails. Lesions under the nail may appear as a longitudinal ridge or groove. Toenail involvement is more common. These typically appear during puberty.

### Cardiac Manifestations

Cardiac rhabdomyomas are present in 50% to 70% of infants with TSC, but they usually remain asymptomatic. These tumors, which are often multiple, decrease in size over time. They are often diagnosed on prenatal ultrasound. Cardiac rhabdomyomas are the most common finding in infants diagnosed with TSC in the first week of life. Complications may include heart failure in infancy and various dysrhythmias, including Wolff-Parkinson-White syndrome.

### Ocular Manifestations

Retinal astrocytic hamartomas are seen in 50% to 87% of patients with TSC, although most remain

**Figure 297-8** Shagreen patches have an orange peel texture and often are located over the lumbosacral spine. (From Krowchuk DP, Mancini AJ, eds. *Pediatric Dermatology: A Quick Reference Guide*. 2nd ed. Elk Grove Village, IL: American Academy of Pediatrics; 2012:461–467.)

asymptomatic. They may be bilateral in up to one-half of patients. Three clinical types include (1) a raised mulberry-like calcified nodule, (2) a flat translucent gray patch, and (3) a transitional lesion with mixed features. Involvement of the macula, enlargement of the hamartoma, vitreous hemorrhage, or retinal detachment may lead to loss of vision. Other ocular findings in TSC may include retinal pigment anomalies, strabismus, cataracts, colobomas, iris depigmentation, and eyelid angiofibromas.

### Renal Manifestations

Renal lesions are the second most common organ system involvement in TSC (after CNS disease), with angiomyolipomas developing in 80% and renal cystic disease in 50% of patients. The prevalence increases with age until adulthood. Angiomyolipomas are found in 55% of 7-year-olds with TSC and 80% of 18-year-olds. Bilateral and multiple tumors are common. Small lesions may remain asymptomatic, but lesions larger than 4 cm pose risks for severe hemorrhage, hypertension, or renal insufficiency. The risk for hemorrhage ranges between 25% and 50%, with 20% to 30% of these patients presenting to emergency departments in shock. The risk for hemorrhage is much higher with aneurysms more than 5 mm in diameter. Renal cysts occur in approximately 17% of children and 47% of adults with TSC. Solitary epithelial cysts are the most common. However, approximately 3% to 5% of patients with TSC will develop polycystic kidney disease as a contiguous gene deletion syndrome because the *TSC2* gene is adjacent to the adult polycystic kidney disease gene *PKD1* on chromosome 16. Polycystic kidney disease may lead to renal insufficiency in late adolescence. Approximately 2% of TSC patients will have severe early-onset polycystic disease. Renal disease may also escalate after acute kidney injury

such as toxic reactions to some anticonvulsants or nonsteroidal anti-inflammatory drugs, or after prolonged seizures. Renal cystic disease is also a significant risk factor for hypertension. Hypertension may also result from the use of adrenocorticotrophic hormone to control infantile spasms. In addition, nephrolithiasis may have increased frequency in TSC because of renal cystic disease, ketogenic diet, and use of drugs such as topiramate. Renal cell carcinoma (RCC) is a less common but potentially severe complication of TSC. Although the lifetime risk for RCC is the same in TSC patients as in the general population, it typically occurs at a much earlier age in TSC patients (average age, 28 years in TSC patients; 52 years in general population). The overall morbidity of renal lesions in TSC is predominantly related to angiomyolipomas.

### Pulmonary Manifestations

Symptomatic lymphangiomyomatosis occurs in 1% to 2% of patients with TSC, almost exclusively in young women. Radiographic evidence of lymphangiomyomatosis may be seen in 26% to 39% of women with TSC. Spontaneous pneumothorax, dyspnea, cough, and hemoptysis are the main clinical findings. This condition is often progressive and is a leading cause of death among women with TSC.

### Vascular Manifestations

Arterial dysplasia is seen most often in renal angiomyolipomas, but it has also been reported with basilar artery and aortic aneurysms.

### Dental Manifestations

Gingival fibromas occur in approximately 50% of adults with TSC. Almost all patients with TSC have dental enamel pits in permanent teeth. The dental pits rarely cause problems, although extensive fibromas may result in malocclusion or abnormal tooth eruption.

### Differential Diagnosis

TSC does not have a pathognomonic lesion; thus, fulfillment of diagnostic criteria is of paramount importance (see Box 297-3). Facial angiofibromas were once considered diagnostic but are now known to occur in multiple endocrine neoplasia syndrome type 1.

### Evaluation

#### History and Physical Examination

In infants, seizures are often the first symptom. Any infant with new-onset seizures should have a detailed history taken, including skin lesions, developmental milestones, and family history. Initial examination should include Wood's lamp examination of the entire skin surface, funduscopic examination for hamartomas, and a thorough neurologic examination. Older children should be screened for seizure disorder, developmental delay, and autism spectrum disorders.

Delay in diagnosis is not uncommon in TSC. Staley and colleagues reviewed records of 243 patients with TSC and found that age at diagnosis ranged from birth to 73 years. Although the average age at diagnosis was 7.5 years, and 81% were diagnosed by age

10 years, 39% of patients were noted to have earlier diagnostic findings. The most commonly missed presenting features were seizures and skin lesions.

### Laboratory Evaluation

Laboratory testing should include an electrocardiogram, especially in infants or children with radiographic evidence of cardiac rhabdomyomas. After criteria are fulfilled for a diagnosis of TSC, molecular testing can be performed to determine the specific mutation. However, 15% to 20% of patients who fulfill TSC diagnostic criteria have no identifiable mutations. Clinical gene testing is available by using combined techniques such as denaturing high-performance liquid chromatography and heteroduplex analysis. Even with combined methods, the mutation detection rate is only 85%.

### Imaging Studies

Imaging studies are valuable for initial evaluation and long-term management of patients with TSC. Initial imaging studies for an infant with TSC include brain studies (MRI or CT), echocardiography, and renal ultrasound. Cortical tubers are best evaluated by MRI. Subependymal nodules may be seen in infancy on MRI as T1-weighted hyperintense nodules. By age 1 year, the subependymal nodules contain calcium and may be visualized with CT scanning. MRI may be useful to identify subependymal giant cell astrocytomas, but radiologic distinction from subependymal nodules is difficult. Renal lesions in older children and adults may be evaluated by ultrasound, CT, MRI, or PET. Chest CT is indicated for all women with TSC to evaluate for possible lymphangiomyomatosis.

### Management

The 2 basic principles of management in TSC are establishment of the correct diagnosis and long-term follow-up for the later manifestations. The treatment of epilepsy in TSC is the same as in other forms of epilepsy (see Chapter 327, Seizure Disorders), with one exception. Infantile spasms in TSC do not respond as well to adrenocorticotrophic hormone as infantile spasms without TSC. The irreversible  $\gamma$ -aminobutyric acid transaminase inhibitor vigabatrin is much more effective, with response rates up to 96% in infants with TSC and infantile spasms. Vigabatrin was approved by the US Food and Drug Administration for infantile spasms in 2009, but concerns remain regarding potential severe ophthalmic toxicity. However, because of the potentially devastating cognitive effect of uncontrolled infantile spasms, vigabatrin may be considered despite its toxicity. With any type of seizures in TSC, better control seems to improve prognosis. Seizures become refractory to treatment in up to 50% of children with TSC.

Neurobehavioral assessment and monitoring are integral to the management of TSC. Routine formal testing should be performed at age-appropriate levels in infancy, preschool, and early school age, and periodically into adulthood to identify cognitive and behavioral issues as early as possible. In addition, any developmental or behavioral regression or new cognitive dysfunction should prompt urgent re-evaluation.

Annual brain MRI is suggested to age 21 years. Annual renal imaging is suggested for monitoring of angiomyolipomas. Serial renal ultrasound is adequate if maximal lesion size is less than 4 cm. Larger renal lesions should be assessed by Doppler, MRI, or magnetic resonance angiography for abnormal vasculature. Screening chest CT for lymphangiomyomatosis is suggested for all women with TSC. Women with lung lesions should have annual pulmonary function tests.

Genetic counseling is mandatory for families and patients with TSC. Because the disorder has autosomal-dominant inheritance, affected individuals have a 50% risk for affected offspring. Germline mutations occur in approximately 2% of patients; thus, seemingly unaffected parents with a single affected child still have approximately a 2% risk for having another affected child.

### WHEN TO REFER

- Ophthalmologic screening: in infancy if TSC is suspected
- Neurologic screening: when seizures are hard to manage or progressive
- Surgery: when symptomatic or progressive renal lesions are larger than 4 cm
- Neurodevelopmental testing: at diagnosis and periodically

### WHEN TO ADMIT

- Sudden neurologic deterioration
- Intractable seizures
- Gross hematuria
- Heart failure or dysrhythmia

## STURGE-WEBER SYNDROME

Sturge-Weber syndrome (SWS), or encephalotrigeminal angiomas, is a rare sporadic disorder characterized by the presence of upper facial port-wine stain (PWS), ipsilateral ocular abnormalities, and ipsilateral leptomeningeal angiomas. Although the syndrome may consist of only 1 or 2 of the triad features, the defining entity is leptomeningeal involvement. SWS has an estimated frequency of approximately 1 in 50,000 live births. It is thought to result from failed regression of the cephalic venous plexus. By the sixth week of embryologic development, a vascular plexus forms around the cephalic part of the neural tube and under the facial skin ectoderm. This plexus usually regresses by the ninth week. In SWS, the plexus persists, with the extent of involvement correlating with the extent of facial and leptomeningeal lesions. No gender predilection has been found. Although a few case reports have suggested familial occurrence, the disorder is thought to result from somatic mosaicism. This concept is supported by discordance between monozygotic twins.

SWS exhibits at birth with an upper facial capillary malformation (PWS), involving the area of skin innervated by the ophthalmic (V1) division of the trigeminal nerve. This area includes the forehead, brow ridge, upper

eyelid, and perhaps the lower eyelid as well. Lower areas of the face (V2 or V3 distributions) may also be involved, but no apparent significant risk for SWS exists in the absence of V1 involvement. Unilateral PWS is the rule, with only 10% to 30% of patients having bilateral PWS. With unilateral facial PWS, the risk for having SWS is approximately 8%, but the risk is much higher if bilateral PWS is present. One of the more useful clinical clues seems to be eyelid involvement, a significant predictor of disease. PWSs are pink to red blanching macules to patches with variable irregularity of the borders (Figure 297-9). They are capillary malformations that remain fixed in location and show no tendency to evolve or involute over time. Growth should be commensurate with the child's growth. With age, the PWS may thicken and darken, becoming somewhat cobbledstoned by adulthood.

Ocular manifestations of SWS may include glaucoma, vascular anomalies of the globe (conjunctiva, episclera, retina, or choroid), buphthalmos, iris heterochromia, retinal detachment, retinal pigment degeneration, cataract, and optic disc coloboma. Glaucoma is the most common ocular problem in SWS, occurring in up to 70% of patients. Glaucoma is usually ipsilateral to the PWS, but it may be bilateral, even if the PWS is unilateral. Although glaucoma may develop from birth to the fifth decade, the median age at onset is 5 years, with 60% developing in infancy to early childhood. Glaucoma developing in infancy, when the globe is more sensitive to increased intraocular pressure, may lead to increased corneal diameter, buphthalmos, or iris heterochromia. Choroidal hemangioma ipsilateral to the PWS is seen in up to 71% of patients with SWS. Choroidal hemangioma is almost always associated with leptomeningeal lesions, making CNS imaging mandatory. Over time, the retinal changes can lead to visual field defects and vision loss.

Neurologic features of SWS may include seizures, focal neurologic deficits, hemiparesis, developmental delay, progressive intellectual disability, or headaches. Seizures are the most common neurologic problem, occurring in 75% to 83% of patients with SWS. Approximately 75% of seizure disorders develop in the first 2 years of life. Partial motor seizures are the most common type (40%), but generalized tonic-clonic,

atonic, and absence seizures may also occur. Infantile spasms may be the presenting seizure type. Seizures tend to worsen with age, becoming more frequent, severe, and complex. Seizures may be provoked by febrile episodes. Status epilepticus may occur in up to one-half of these children. Earlier onset may predict worse outcome, with poor seizure prognosis, more difficult seizure control, and higher risk for cognitive impairment, although this is somewhat controversial. Bilateral leptomeningeal angiomas (7%–26% of patients) has a poor neurologic prognosis. Some patients may develop sudden episodes of weakness, even in the absence of seizures. These episodes are stroke-like and may be transient or may leave permanent hemiplegia. Hemianopsia may develop in up to one-half of SWS patients.

Developmental delays are seen in up to one-half of patients with SWS. Early milestones are often normal, with decline in function noted over time. At least some of the cognitive decline occurs during periods of encephalopathy after prolonged or severe seizures, whereas other patients experience decline in function as a result of recurrent stroke-like episodes. Factors that seem to correlate best with developmental delay and its severity are presence of bilateral cerebral lesions, degree of cerebral atrophy, presence of intractable seizures or multiple seizure types, and possibly early onset of seizures, although the last of these factors remains controversial. In the absence of seizures, cognitive development is normal. Furthermore, 85% of patients with seizure onset after age 4 years have normal intelligence.

Psychological manifestations of SWS may include ADHD, irritability, and social problems. Inattentive and oppositional behaviors may be noted. Approximately 85% of patients with SWS who have intellectual disability exhibit emotional or behavioral problems, including aggressive behavior toward others and self-abuse.

Headache, including migraine, is seen in 30% to 45% of individuals with SWS. The median age at onset is 8 years. Migraines may be associated with visual aura and visual field defects.

### Differential Diagnosis

The differential diagnosis of SWS includes isolated (ie, nonsyndromic) facial PWS and Wyburn-Mason syndrome. Unilateral forehead PWS has no underlying syndrome in 92% of patients. Bilateral PWS, in contrast, has a much higher likelihood of association with SWS. Wyburn-Mason syndrome is a rare disorder consisting of retinal and CNS arteriovenous malformations associated with upper facial PWS. Headaches, seizures, focal neurologic deficits, retinal hemorrhage, and subarachnoid hemorrhage may occur.

### Evaluation

#### History

The earliest manifestation of SWS is the PWS present at birth. Relevant history in a child with facial PWS should include history of seizures, history of eye or vision problems, and any concerns about development. Older children should be asked about headaches, vision changes, episodes of weakness, and school progress.

**Figure 297-9** Port-wine stain in Sturge-Weber syndrome.

### Physical Examination

Examination of any child with facial PWS should include a thorough eye examination. Any difference in sizes of cornea or globe, or any iris heterochromia, may be a clue to early glaucoma. Presence of PWS on eyelids should be noted. Auscultation of the orbits, fontanels, and temples should be performed to detect bruits. Funduscopic examination might reveal the characteristic *ketchup stains* of choroidal angiomas. Tortuous vessels or colobomas should be noted. Neurologic examination should search for focal deficits. Developmental evaluation is important, particularly if the child has a seizure history. Observation of an infant should specifically address the presence of a head turn or early handedness, which are potential clues to visual field cuts.

### Laboratory Evaluation

Routine laboratory testing is not useful in SWS. Evaluation of seizures should include electroencephalography. The typical findings include asymmetry, with background slowing and reduced voltage in the affected hemisphere. The asymmetry becomes more prominent with the progressive cerebral atrophy.

### Imaging Studies

The most sensitive imaging modality to evaluate for leptomeningeal angiomas is gadolinium-enhanced MRI. Leptomeningeal enhancement, with or without cortical atrophy, is the radiologic hallmark of SWS. The leptomeningeal involvement is ipsilateral to the PWS. It may be seen before calcifications develop. Calcification of adjacent gyri may give the classic *tram track* appearance seen on CT and even plain-film radiographs (although the latter rarely are used). Involvement of the parietal and occipital lobes is often noted before frontal or temporal findings. Positron emission tomography and single-photon emission CT may reveal areas of altered metabolism and hypoperfusion. Chronic venous engorgement leading to reduced perfusion is thought to be the mechanism underlying progressive cerebral atrophy in SWS. Choroidal angiomas are best visualized with MRI.

### Management

Infants with facial PWS on the forehead and eyelids should be evaluated for the possibility of SWS. Evaluation should include ophthalmologic examination. If eye findings or any other typical clinical features, such as seizures, are present, then neuroimaging is mandatory. Routine MRI may be performed even in the absence of seizures because prophylactic anticonvulsant therapy may be useful for infants with extensive intracranial disease. Seizure control is the most important aspect of management because seizure activity may further compromise cerebrovascular function and lead to worse neurologic decline. Carbamazepine and oxcarbazepine are useful first-line anticonvulsants for SWS. Valproic acid, topiramate, phenobarbital, phenytoin, and vigabatrin have also been suggested. (For a thorough discussion of anticonvulsant therapy, see Chapter 327, Seizure Disorders.) Refractory seizures in SWS may lead to consideration of seizure surgery.

Hemispherectomy and focal resection have both been found to reduce refractory seizures and improve developmental outcomes. Avoiding fatigue, sleep deprivation, stress, and minor head trauma may help prevent headaches. Glaucoma may be managed medically in most patients with  $\beta$ -adrenergic blockers or carbonic anhydrase inhibitors. Surgical approaches are not usually required. PWS may be treated effectively with pulsed dye laser.

### WHEN TO REFER

- Ophthalmologic evaluation: any infant with forehead and eyelid PWS
- Neurologic evaluation: difficult seizure management

### WHEN TO ADMIT

- Refractory seizures

## VON HIPPEL-LINDAU DISEASE

Von Hippel-Lindau disease (VHL) is an autosomal-dominant multiorgan familial cancer syndrome. Prevalence is estimated at about 1 in 36,000 live births. The disease is inherited in 80% of patients, with the remainder representing new mutations. The disease is more than 90% penetrant by age 65 years. The *VHL* gene is a tumor suppressor gene found on chromosome 3. The normal gene product is part of a protein complex responsible for ubiquitination of hypoxia-inducible factors, leading to their degradation. With functional loss of the VHL protein, these hypoxia-inducible factors trigger transcription of vascular proliferation mediators, including vascular endothelial growth factor, platelet-derived growth factor, transforming growth factor- $\alpha$ , and erythropoietin. These growth factors then lead to unregulated endothelial and vascular proliferation to produce vascular neoplasms. Erythropoietin production may lead to development of polycythemia, including the nontumoral syndrome Chuvash polycythemia, which also is caused by a mutation in the *VHL* gene. The mechanism of nonvascular tumorigenesis remains uncertain. Almost all patients with VHL have germline mutations in the *VHL* gene, as well as secondary somatic mutations (Knudson two-hit hypothesis). VHL is subdivided into 2 major categories that are based on the type of mutation. Type 1 disease mutations are premature termination mutations or deletions, whereas type 2 disease is characterized by missense mutations. Phenotypically, type 1 disease is not associated with significant risk for pheochromocytoma, whereas pheochromocytoma is a predominant tumor in type 2 disease. Further subdivisions are listed in Table 297-3. The diagnosis of VHL is established in a patient who has 1 characteristic tumor and a positive family history, or hemangioblastoma plus 1 other tumor when the family history is negative. The most common tumors in VHL are cerebellar, spinal, and retinal hemangioblastomas. The other associated tumors include renal cysts, RCC, pheochromocytoma, pancreatic cysts or neuroendocrine tumors, endolymphatic sac tumors of the inner

Von Hippel-Lindau disease: molecular pathological basis, clinical criteria, genetic testing, clinical features of tumors and treatment. *Jpn J Clin Oncol*. 2006;36:337–343.

ear, and cystadenomas of the epididymis or broad ligament. The major causes of death are RCC and complications from CNS hemangioblastomas.

CNS hemangioblastomas are the most common tumors in VHL (60%–84% of patients). They occur most commonly in the cerebellum (63%), followed by the spinal cord (32%) and brainstem (5%). The mean age at presentation is 33 years, but tumors may develop in childhood (younger than 10 years) through the fourth decade of life. These slow-growing benign tumors produce symptoms largely by mass effect or obstructive hydrocephaly. Cerebellar tumors may present with headache, nausea, vomiting, vertigo, slurred speech, and broad-based gait. Clinical signs may include papilledema, nystagmus, ataxia, and dysmetria. Spinal hemangioblastomas may produce back pain, numbness, pain or weakness in arms or legs, posterior column proprioceptive defects, or incontinence. CNS hemangioblastomas tend to exhibit alternating periods of growth and stability so that low-level chronic symptoms may worsen acutely during a critical growth phase. These tumors or retinal tumors are commonly the first symptomatic lesions of VHL. Although histologically benign, these CNS lesions are a major source of mortality in VHL.

Retinal hemangioblastomas (capillary hemangiomas) develop in more than one-half of patients with VHL. Although most of these patients have solitary tumors, approximately one-third will have multiple lesions, and one-half will have bilateral retinal tumors. Most of these lesions develop in the second to third decades of life, with mean age at diagnosis of 25 years. However, retinal tumors may develop at any time from infancy to the ninth decade. Patients may experience painless loss of visual acuity or visual field defects, although they may remain asymptomatic. Exudation or hemorrhage from the hemangiomas may lead to macular edema or retinal detachment. Secondary changes in the anterior chamber may lead to glaucoma or cataract.

Renal cysts are seen in approximately one-half of patients with VHL. Often multiple and bilateral, they may remain asymptomatic, but are considered premalignant. Stable lesions may not require intervention. RCC develops in 75% of patients with VHL by age 60 years. RCC is seen in patients with type 1 or 2b disease. The typical histologic type is the clear cell type. It usually develops after 20 years of age, although often

earlier than with sporadic renal carcinoma. Lesions are frequently multiple and bilateral. The tumors may be associated with cysts and may have a better 10-year survival than sporadic RCC. However, metastatic RCC is a leading cause of death in patients with VHL. Symptoms may include hematuria, flank pain, or flank mass. By the time symptoms develop, metastases are present in 30% to 50% of patients.

Pheochromocytoma occurs in type 2 disease with a frequency of 10% to 24% and may be the only manifestation of VHL (type 2c). VHL accounts for approximately 20% of all pheochromocytomas. Mean age at presentation is 27 years, but tumors may be present even before age 10 years. In the pediatric age group, pheochromocytoma may be the presenting feature of VHL, with severe hypertension or hypertensive crisis as the most frequent presentation. Pheochromocytoma in VHL differs from sporadic tumors by occurring at an earlier age and by developing multiple, bilateral, and extra-adrenal tumors in VHL. Only 5% of VHL pheochromocytomas are malignant. Clinical features may include hypertension (paroxysmal or sustained), palpitations, sweating, flushing, headache, tachycardia, pallor, and nausea.

Pancreatic cysts or tumors occur in approximately 35% to 77% of patients with VHL in most series, but most are benign. Benign cystadenomas occur in approximately 12% of patients with VHL. Approximately 9% to 17% of patients with VHL will develop neuroendocrine tumors. The latter may be multifocal and may metastasize in 10% to 20%. The mean age at diagnosis of pancreatic lesions is 29 to 38 years, although islet cell tumors may be seen as early as 10 years of age. Most pancreatic lesions are asymptomatic and are found during routine imaging surveillance, but malignant tumors have been reported in up to 50% of VHL patients.

Approximately 10% of patients with VHL will develop endolymphatic sac tumors. These locally invasive papillary cystadenomas arising from the inner ear labyrinth ectoderm may cause deafness, tinnitus, or vertigo. Facial nerve and vocal paralysis may result from progressive tumor growth. The hearing loss is irreversible and presents at an average age of 22 years.

Finally, cystadenomas may develop in the epididymis in men and the uterine broad ligament in women. These are usually asymptomatic.

**Table 297-4** Differential Diagnosis of Retinal Capillary Hemangioma in von Hippel-Lindau Disease

CONDITION	FEATURE	PRESENCE OF RETINAL OR SUBRETINAL EXUDATES
von Hippel-Lindau disease	Orange-red circumscribed tumors Pair of prominent vessels Stellate macular exudates	Yes
Coats disease	Diffuse retinal vascular anomaly	Yes
Wyburn-Mason syndrome	Dilation and tortuosity of retinal arteries and veins, but no intervening hemangioma	No
Retinal cavernous hemangioma	Cluster of small dilated vessels around central vein Lack of prominent feeder vessels	No
Vasoproliferative tumor of the retina	Pink to yellow retinal tumor Lack of dilated feeder vessels Lack of stellate macular exudates	Yes (nonstellate)

Derived from Magee MA, Kroll AJ, Lou PL, et al. Retinal capillary hemangiomas and von Hippel-Lindau disease. *Semin Ophthalmol.* 2006;21:143–150.

### Differential Diagnosis

Central nervous system hemangioblastomas create symptoms by mass effect, as with many other tumors, cysts, and obstructive hydrocephalus. Evaluation of mass effect with neurologic symptoms should reveal the characteristic radiologic findings of hemangioblastomas. The differential diagnosis of retinal capillary hemangiomas is provided in Table 297-4. The differential diagnosis of renal cysts includes the diagnosis of polycystic kidney disease. Pheochromocytoma may occur sporadically or may occur in the setting of VHL, multiple endocrine neoplasia type 2a or 2b with associated medullary thyroid carcinoma, or neurofibromatosis, or with succinate dehydrogenase subunit mutations.

### Evaluation

#### History

The most important historical information is family history because 80% of cases are familial. Other relevant history might include changes in vision; development of neurologic symptoms such as clumsiness, broad-based gait, hearing loss, slurring of speech, pain, numbness or weakness in limbs, or loss of bowel or bladder control after complete toilet training; hematuria or flank pain; heart palpitations, flushing, or sweating spells; or episodic nausea and vomiting.

#### Physical Examination

Physical examination should include regular blood pressure evaluation, thorough eye examination, and thorough neurologic examination with particular attention to cerebellar and spinal functions. Observation of gait, test of balance, deep-tendon reflexes, and test for sensation should be included in the examination.

#### Laboratory Evaluation

Laboratory testing in VHL should begin with molecular testing for the specific mutation in the *VHL* gene because the phenotypic profile and tumor risk are directly related to the types of mutation. Identification of

*VHL* mutation carriers early in life is critical to determine the type of tumor risk and the necessary ongoing surveillance the child will need. It is particularly important to identify those at risk for retinal disease because early detection of intraocular tumors can lead to prompt vision-saving therapy. Subsequent laboratory evaluation for patients with type 2 disease should consist of annual screening for plasma or urine catecholamines and metanephrines beginning at age 10 years. The typical profile in VHL pheochromocytoma is noradrenergic, with norepinephrine elevations representing 98% of these patients.

#### Imaging Studies

Magnetic resonance imaging with gadolinium contrast is the modality of choice for most of the features of VHL. Hemangioblastomas of the cerebellum are usually subpial in location. They may appear as a solid enhancing mass with or without surrounding fluid space or as a more complex tissue or fluid mass. Spinal hemangioblastomas are solid enhancing intramedullary masses frequently associated with a surrounding fluid-filled syrinx that enlarges and displaces the cord. Renal cysts may be found on MRI, ultrasound, or CT. Endolymphatic sac tumors can be detected on MRI or CT imaging. Localization of pheochromocytomas requires use of 2 imaging modalities, often MRI or CT coupled with MIBG or octreotide scintigraphy, PET, or dopamine and deoxyglucose scans.

#### Management

The most important aspect of management in VHL is regular screening for the various tumors. First-degree relatives should also be screened for tumors. After a diagnosis is established, regular imaging and ophthalmologic examinations are indicated. Eye examinations, including dilated funduscopy, should begin by age 6 years and should be repeated annually. Annual cranial and spinal MRI should begin by age 10 to 11 years. Abdominal imaging for kidneys and possible pheochromocytoma should begin by age 15 to 18 years and may consist of ultrasound, CT, or MRI, with MRI

being the best modality for finding all the possible intraabdominal tumors (renal, pheochromocytoma, and pancreatic). Hearing loss or tinnitus should be evaluated by MRI with thin sections through the ear structures, as well as formal audiologic examination. Lifelong surveillance is required, even after excision of tumors, because of both late-onset presentation of new tumors and the risk for late tumor recurrences.

Surgical excision is generally considered the best treatment for most symptomatic VHL tumors. CNS hemangioblastomas that remain stable and asymptomatic may be followed by serial imaging. Proper management for asymptomatic, but radiologically progressive, lesions is a matter of debate. Spinal hemangioblastomas and large or symptomatic intracranial tumors are generally resected. Small retinal lesions are often treated with laser photocoagulation; larger lesions may require cryotherapy, brachytherapy, or vitreoretinal surgery. Screening for eye lesions is of critical importance because the visual prognosis is better when ocular lesions are detected before development of symptoms. Small renal tumors (<3 cm) are often followed by serial imaging. Larger lesions may be addressed by partial nephrectomy. Radical nephrectomy is rarely indicated. Pancreatic tumors larger than 3 cm are generally resected. Almost all metastatic pancreatic tumors have at least 2 of the following features: size larger than 3 cm, mutations in exon 3 of the *VHL* gene, or a tumor doubling time of less than 500 days. Symptomatic pheochromocytomas require excision. Laparoscopic removal of both adrenal and extraadrenal tumors is now favored, with its lower complication rate.

#### WHEN TO REFER

- Ophthalmologic examination: by age 6 years; with any sudden vision change
- Neurologic examination or neurosurgery: on detection of CNS tumors
- General surgery: on detection of intra-abdominal tumors
- Audiology: at diagnosis, or at onset of auditory symptoms

#### WHEN TO ADMIT

- Hypertensive crisis with pheochromocytoma
- Sudden neurologic deterioration

### ATAXIA-TELANGIECTASIA

Ataxia-telangiectasia (A-T), or Louis-Bar syndrome, is an autosomal-recessive progressive neurodegenerative disorder with a frequency of 1 in 40,000 in the United States to 1 in 300,000 in the United Kingdom. Consanguinity is a common finding. The characteristic features are progressive decline in cerebellar function, oculocutaneous telangiectasia, immunodeficiency, susceptibility to cancer, and sensitivity to ionizing radiation. A-T is caused by mutations in the *ATM* (ataxia-telangiectasia, mutated) gene. The ATM protein is a nuclear serine-threonine protein kinase that acts as a regulator of many cellular control pathways. Its primary function seems to be

mobilization of cellular responses to breaks in double-stranded DNA. After a DNA break occurs, *ATM* activates numerous proteins involved in DNA repair, apoptosis, and control of cell cycling. Loss of *ATM* function leads to accumulation of defective DNA and inability to repair or eliminate genetically defective cells. Defective DNA repair explains the sensitivity to ionizing radiation, whereas inability to remove damaged cells has been postulated as a cause of many of the diverse abnormalities in A-T. Similarly, cancer has been linked to genomic instability, helping explain the cancer risks in A-T.

Infants with A-T are normal; they begin to walk at approximately age 12 months. However, by age 2 to 3 years, they develop unsteady gait and staggering. Choreoathetosis begins soon thereafter. Dystonia or choreoathetosis develops in 90% of patients with A-T. By age 10 years, most children require wheelchairs for mobility because they have slow reflexes and tend to fall. Ocular apraxia (difficulty with voluntary eye movement), which may be confused with absence seizures in infants, develops in early childhood. Similarly, dysarthric speech is often present early in childhood but can be difficult to assess.

Telangiectasias (tortuous dilated capillaries) develop several years after the onset of neurologic symptoms. They are found on the bulbar conjunctiva, nasal bridge, ears, neck, knuckles, and both antecubital and popliteal fossae.

Immunodeficiency varies but may be severe in approximately one-third of patients with A-T. Many patients have reduced numbers of T lymphocytes with poor mitogen response. Low serum levels of immunoglobulin (Ig) E (80% of patients), IgG<sub>2</sub> (80%), and IgA (60%) are noted despite normal to high numbers of B cells. In addition, IgM levels vary widely, at times rising enough to create a hyperviscous state. Some patients exhibit poor immune response to pneumococcal polysaccharides. Patients with severe immunodeficiency may develop recurrent sinopulmonary infections. However, opportunistic organisms are not a problem in patients with A-T. Patients with A-T are at higher risk (one-third) for developing cancer. In children, acute lymphoblastic leukemia predominates, followed by other lymphoid tumors such as B-cell non-Hodgkin lymphoma, T-cell lymphoma, and Hodgkin disease. Older children sometimes develop T-prolymphocytic leukemia. Adults tend toward non-lymphoid cancers such as breast, stomach, ovarian, liver, and uterus cancers, melanoma, and basal cell skin cancer. Women who are *ATM* mutation carriers have a 5-fold increase in risk for breast cancer compared with the noncarrier population. Approximately 15% of patients with A-T die from lymphoid malignancies during childhood.

Because of the inability to repair defective DNA, patients with A-T are also susceptible to injury by ionizing radiation and radiomimetic chemotherapeutic drugs. This susceptibility complicates therapy for the various malignancies and poses a life-threatening risk to patients with A-T exposed to these agents.

#### Differential Diagnosis

The differential diagnosis of A-T is provided in Table 297-5.

**Table 297-5** Differential Diagnosis of Ataxia-Telangiectasia

CONDITION	NEUROLOGIC FEATURES	PRESENCE OF TELANGIECTASIA	INCREASED $\alpha$ -FETOPROTEIN	CANCER RISK	IMMUNE DEFICIENCY	SENSITIVITY TO RADIATION
Ataxia-telangiectasia	Early ataxia, oculomotor apraxia, progressive neurologic decline	Yes	Yes	Yes	Yes	Yes
Ataxia-telangiectasia-like disorder ( <i>hMRE11</i> mutation)	Ataxia early	No	No	No	No	Yes
Nijmegen breakage syndrome	Microcephaly, intellectual disability	No	No	Yes	Yes	Yes
Ataxia oculomotor apraxia type 1	Early ataxia, progressive neurologic decline	No	No	No	No	No
Ataxia oculomotor apraxia type 2	Late-onset ataxia	No	Yes	No	No	No

Adapted from Chun HH, Gatti RA. Ataxia-telangiectasia, an evolving phenotype. *DNA Repair (Amst)*. 2004;3:1187–1196; Perlman S, Becker-Catania S, Gatti RA. Ataxia-telangiectasia: diagnosis and treatment. *Semin Pediatr Neurol*. 2003;10:173–182; and Taylor AM, Byrd PJ. Molecular pathology of ataxia telangiectasia. *J Clin Pathol*. 2005;58:1009–1015.

### Evaluation

The earliest manifestation of A-T is the ataxia, beginning as broad-based gait or staggering by age 2 to 3 years. Any other history should focus on additional neurologic symptoms and developmental milestones. Additional history should include the presence of similar neurologic problems or consanguinity in the family.

Examination should focus on neurologic findings, including cerebellar function. Although difficult to assess in young children, voluntary visual tracking of objects will often reveal the early development of oculomotor apraxia. In older children, telangiectasia may be noted on the bulbar conjunctiva and on the skin of the neck, face, ears, and extremity flexures. The examination should include thorough lymph node examination and abdominal evaluation for hepatosplenomegaly.

Laboratory testing in suspected A-T should include serum  $\alpha$ -fetoprotein, which is increased in more than 95% of patients with A-T. Serum  $\alpha$ -fetoprotein increase is only useful beyond age 2 years because some children have persistent mild increases beyond the neonatal period. Karyotyping is rarely normal in A-T, often showing translocations between chromosomes 7 and 14. Quantitative immunoglobulins may show low levels of IgE, IgA, and IgG2. IgM is normal or high. Quantitative T- and B-cell numbers will reveal low levels of T cells, but normal to slightly high levels of B cells. The only radiosensitivity test currently available is the colony survival assay, which uses the patient's transformed lymphocytes. It requires approximately 3 months to complete. Gene testing is not useful unless the family mutation is known because *ATM* is a huge gene with 66 exons and more

than 400 known mutations (none with a frequency of more than 3%). Measurements of the ATM protein from the transformed lymphocyte cell line is also possible (by immunoblotting).

Imaging in A-T is limited. Cranial MRI will reveal gradual cerebellar atrophy, almost always noted by age 10 years. Imaging with radiation should be considered carefully because of these patients' extreme radiosensitivity. Adult female patients and carriers should be screened for breast cancer with regular examinations and ultrasound, but not mammograms.

### Management

The most important aspects of therapy in this degenerative condition are family and patient counseling and support, followed by rehabilitation and assistance with the progressive ataxia. Speech, physical, and occupational therapy should be obtained early to help the child and family with the problems that arise over time. Speech therapy may help with the communication and swallowing difficulties, whereas mobility, safety, and daily living skills can be supported by physical and occupational therapy. Careful monitoring is crucial for the recurrent infection and cancer risks. Recurrent sinopulmonary infections should be treated aggressively, and aspiration should be anticipated. Although ionizing radiation is of concern in these patients, it is imperative to diagnose pulmonary disease early, and chest radiographs deliver relatively little radiation compared with other modalities. Emotional support is crucial, with depression, anger, and isolation occurring frequently.

Life expectancy varies, but survival into the sixth decade is likely. The leading causes of death are malignancy, infection, and pulmonary failure (the latter from combined recurrent infection and recurrent aspiration).

### WHEN TO REFER

- Neurologic examination: on development of ataxia
- Speech therapy: on development of speech or swallowing difficulty
- Physical and occupational therapy: before ataxia becomes severe

### WHEN TO ADMIT

- Severe pulmonary infection, especially if respiratory distress is present
- Severe aspiration event

## Chapter 298

# OBESITY AND METABOLIC SYNDROME

Helen Chieh-yu Wang, MD; Sheila Gahagan, MD, MPH

## INTRODUCTION

Childhood obesity has reached epidemic proportions in the United States and worldwide. The US continues to have a high prevalence of obesity with one-third of all adults and one-sixth of all children aged 6 to 19 years classified as obese. The medical complications associated with obesity, including non-insulin dependent diabetes mellitus, hypertension, and dyslipidemia, continue to rise. In the US, total health care expenses for obesity now exceed those for smoking. The cause of this epidemic is multifactorial, including biologic, psychologic, environmental, and social factors. Despite tremendous research efforts, an inadequate understanding of risk factors and protective factors remains. Furthermore, strategies to prevent and treat childhood obesity need to be developed and evaluated. Child health professionals play a crucial role in preventing further escalation of this epidemic and in treating people who are already affected.

## DEFINITIONS

The terms *overweight* and *obese* commonly are used to describe adiposity in the adult population. The currently accepted definitions of overweight and obesity in children and adults are based on body mass index (BMI). Body mass index is weight in kilograms divided by height in meters squared. This calculation has been validated as an approximation of a person's body fat and correlates well with medical complications associated with obesity; BMI is also easily calculated from standard measurements obtained during health care visits. The Centers for Disease Control and Prevention provide age- and sex-specific growth curves for BMI. Electronic medical records allow for routine calculation and plotting of BMI when height and weight data are entered into the record.

In adults, a BMI of 25 or greater is considered overweight, whereas a BMI of 30 or greater is obese. In children, fat mass percent changes throughout development; therefore, BMI percentiles are used to correct for age and gender. Normal BMI trajectories include a decrease in BMI during the preschool years followed by an increase beginning at 5 to 6 years and continuing through adolescence, stabilizing in early adulthood. For children and adolescents, overweight is defined as a BMI at or above the 85th percentile and below the 95th percentile. Obese is defined as a BMI at or above the 95th percentile.

## EPIDEMIOLOGY

Between the 1960s and 2010, the prevalence of obesity dramatically increased worldwide in developed and underdeveloped countries. Only the very poorest geographic areas where food scarcity is widespread, such

as Haiti and sub-Saharan Africa, have yet to be affected. Although worldwide obesity prevalence continues to rise, the prevalence has not been increasing over the last decade in the United States and in several European countries.

The most recent US data from the 2011 to 2012 National Health and Nutrition Examination Survey reveals that 35% of US adults were obese and an additional 34% were overweight. In children and adolescents from 6 to 19 years old, 17% were obese and 15% were overweight. The obese and overweight prevalences in children 2 to 5 years old were 8% and 19%, respectively. In this age group over the last decade, obesity prevalence declined by 43%, suggesting that public health strategies are working. Among infants and toddlers from birth to 2 years old, 8% had weight-for-length percentiles at or above the 95th percentile.

Disparities in obesity prevalence by race, Hispanic origin, and sex remain important. Among non-Hispanic blacks 6 to 19 years old, 23% were obese and 16% were overweight. Similarly, among Hispanic youth 6 to 19 years old, 24% were obese and 18% were overweight. Hispanic boys and non-Hispanic black girls show particular risk, with 44% and 40%, respectively, being overweight or obese. Although adult studies show an inverse relationship between socioeconomic status (SES) and obesity, the relationship between SES and obesity in children is more complicated. Poverty seems to be a risk factor for obesity in non-Hispanic white adolescents; however, no association between SES and obesity has been found in Hispanic youth. Conversely, higher SES is associated with higher rates of overweight and obesity in blacks. Further research is needed to understand the role played by family income in determining nutrition and physical activity patterns.

Childhood obesity is associated with obesity in adulthood. Of children who are obese from 6 to 11 years of age, 50% of girls and 30% of boys are expected to be obese as adults, compared with 18% of nonobese age-matched peers. Obesity during adolescence poses even greater risk with more than 60% of obese adolescents expected to remain obese into adulthood. Obese adults who became obese during childhood are more likely to have severe obesity (BMI >40) than those who become obese during adulthood.

Parental obesity is the most important identified risk factor for developing obesity before young adulthood. For children younger than 3 years, parental weight is a better predictor of adult obesity than the child's actual weight. This effect lessens as children age, with the child's weight becoming an equal predictor at school age and a more important predictor at adolescence. Both overweight and normal-weight children who have one obese parent are at twice the risk for adult obesity compared with children who do not have an overweight parent. Of overweight 10- to 14-year-olds with at least one obese parent, 80% remain obese as adults. Although genetic influences may be important, the rapid rise in obesity over the last 20 years demonstrates that lifestyle and societal influences clearly play a significant role. The fact that children and parents share neighborhood and family

environmental conditions further supports the importance of causal environmental factors. Understanding genetic contributions to childhood obesity will allow more targeted prevention and intervention efforts.

## **PATHOPHYSIOLOGIC FEATURES**

Weight gain is caused by a positive energy imbalance resulting from excessive caloric intake, inadequate energy expenditure, or a combination of the two. Even small surpluses in energy balance over time can have important effects. Estimates suggest that a sustained positive balance of 100 calories per day leads to a weight gain of 10 pounds per year. A common myth is that a slow metabolism causes obesity. However, overweight and normal-weight children do not differ by metabolic rate. Furthermore, overweight adolescents have higher total daily energy expenditures and resting energy expenditures than adolescents who are not overweight. Therefore, overweight children need to eat more to maintain their higher body weight.

Higher prepregnancy maternal BMI is associated with more rapid infant growth and higher risk for later obesity in the infant. Higher birth weight also correlates with later obesity. Sensitive periods of risk for the development of obesity include infancy, adiposity rebound (typically at 5 to 6 years old), and adolescence. Infant BMI is high at birth and increases slightly for the first months of infancy and then declines for 5 to 6 years before gradually increasing toward adult levels. The nadir between 5 and 6 years has been called adiposity rebound. Early adiposity rebound is associated with an increased risk for childhood obesity. During adolescence, a time of significant growth, there are notable changes in fat distribution and body composition that differ by gender. In boys, fat mass decreases by approximately 40%, whereas in girls it increases by approximately 40%. Gender differences in the risk for adult obesity may relate to increasing fat mass during adolescence. Obese and overweight adolescent girls are more likely to remain obese than obese and overweight adolescent boys. Only 20% of overweight girls normalize their weight in adulthood, whereas almost 70% of overweight male adolescents develop normal adult BMI.

The family and food environment are important determinants of obesity. Family environment plays a role in the development of food choices, with many food preferences established by 2 to 3 years old. Food preferences and feeding behaviors relate to the availability of specific foods, role modeling by caregivers, and positive and negative reinforcement of the child's choices. This fact may explain why children of overweight parents are more likely to prefer high-fat foods compared with children of normal-weight parents. Obese children consume less at breakfast and more at dinner than their normal-weight peers. Skipping breakfast is also associated with poorer food choices and increased risk for obesity. Families who eat meals together consume less fried food and carbonated beverages and more fruits and vegetables. Healthy eating in families may come as a package: eating 3 meals a day, preferably together, and choosing nutritional foods.

Eating behaviors and appetite regulation—the response to hunger and satiety—are at least partially conditioned. Overeating can develop in response to environments that interfere with normal regulatory mechanisms, as seen with extremes of parental behavior, including neglect and overinvolvement. Over-protective parents have been shown to use food to comfort their children. Parents who prompt their children to finish what is on their plate may actually impair children's ability to self-regulate appetite and satiety. Overweight children have been found to eat faster and to slow their eating less at the end of meals, suggesting a decreased sensation of satiety. Feeding habits, which may be learned from caregivers early in life, can have a lasting effect on a child's eating habits and preferences.

Food insecurity may also place individuals at higher risk for obesity. Malnutrition during gestation and early infancy are associated with risk for obesity. Possible mechanisms include overeating and excess deposition of fat when adequate food is available. It is also possible that individuals develop increased sensitivity to hunger- and satiety-related hormones and neurotransmitters, resulting in fat deposition in response to early life stress. Further research is needed to determine whether the development of signaling pathways, entrainment of adipocytes, or other factors during the prenatal period and early infancy might explain long-term regulation of adiposity.

The neuroendocrine regulation of ingestive behavior involves the dopamine system, which also modulates learning, motivation and reward, and appetite. Leptin, a hormone that acts on the hypothalamus to regulate hunger and satiety, is secreted by adipocytes. Leptin may be able to reduce the reward value of food because increased leptin signaling decreases food intake. Serum leptin levels correlate with adiposity in both children and adults. Whether increased adiposity results in decreased leptin production or whether primary leptin deficiency is followed by weight gain is unclear. Leptin resistance or deficiency results in an increased food intake in animal models.

## ETIOLOGY

Environmental changes over the last few decades, including urbanization, technologic advances, and easy access to calorie-dense foods, are related to population-level increases in obesity prevalence. Urbanization and urban sprawl have contributed to more sedentary lifestyles because of an increased reliance on motorized transportation. Fewer children walk to school today than they did in the past (Box 298-1). Furthermore, many families perceive their neighborhoods as unsafe and therefore limit their children's outdoor playtime. Even for those whose neighborhoods are considered safe, outdoor playtime has decreased for US children. Technologic advances also have contributed to decreased activity, with children devoting time to television, video games, and computers. Television time of more than 3 hours per day has been associated with a higher average BMI. Screen time displaces more active pursuits and can displace or disrupt sleep. Furthermore, children are the targets of advertising for high-calorie foods and beverages. For these

### BOX 298-1 Activity and Nutrition Changes Over the Last Two Decades

#### ACTIVITY

- Increased screen time (television, video games, computer)
- Decreased physical education in schools
- Decreased walking to school
- Decreased outdoor play time

#### NUTRITION

- Increased sugar-sweetened beverages (including juice)
- Increased fast-food consumption
- Increased fat in school lunches
- Increased portion size
- Decreased family meals

reasons, the American Academy of Pediatrics supports limiting screen time.

Short sleep duration has been associated with increased risk for obesity in children and adults. The biologic mechanisms behind this association are increasingly well understood. Alterations in insulin, leptin, ghrelin, and cortisol result in insulin resistance, sympathetic nervous system activity, hunger, and lower satiety. Sleep-restricted individuals exercise less, eat more, and are likely to consume more calories as fat. Environmental factors that increase risk for short sleep include early school start times for adolescents, caffeine use, and overscheduling related to academics and extracurricular activities. In addition, light from screens (televisions, computer, and other devices) seems to suppress melatonin release, resulting in circadian rhythm disruption.

Obesity can also lead to sleep problems, especially obstructive sleep apnea. Children with snoring, restless sleep, and behavioral problems should be evaluated for possible sleep apnea, using polysomnography. The development of obstructive sleep apnea and disrupted sleep can lead to shorter sleep, which in turn exacerbates obesity.

Dietary habits also changed rapidly after 1960, with larger portion sizes, greater intake of calorie-dense beverages and juice, and increases in consumption of fast-food meals. Servings of sugar-sweetened beverages correlate with risk for obesity. Although the US Department of Agriculture federal school lunch program specifies that no more than 30% of calories may be from fat, many schools provide foods from fast-food contractors, resulting in an availability of high-fat foods. Furthermore, vending machines in schools often provide sugar-sweetened beverages and snack foods (see Box 298-1). Consequently, lunch at school may contain excess calories, with more than 30% of calories from fat.

## MEDICAL COMORBIDITY

Obesity is associated with medical comorbidities in many organ systems. Although some problems are apparent after a relatively short duration of excess

body fat, other complications do not arise for decades. Nonetheless, obesity is responsible for the childhood onset of diseases previously seen only during adulthood, most notably type 2 diabetes mellitus.

Cardiovascular complications of obesity include hypertension and dyslipidemia. Hypertension is defined as a systolic or diastolic blood pressure at or above the 95th percentile for age, sex, and height. Hypertension continues to be underdiagnosed in children, in part because blood pressure norms change with height, age, and gender. Furthermore, technical difficulties, including the use of the wrong-sized blood pressure cuff, can cause errors. The prevalence of diastolic hypertension increases with BMI, and the prevalence of hypertension is 3 times greater in overweight children compared with their normal-weight peers. Disturbances in autonomic function and abnormalities in vasculature may play important mediating roles in the development of hypertension in obese children. As little as 5 to 10 pounds of weight loss can lead to a decrease in blood pressure. (See Chapter 163, High Blood Pressure.) Obesity in adults and children leads to increased concentrations of triglycerides and decreased high-density lipoprotein (HDL) cholesterol. Obese individuals have an increased hepatic production of triglyceride-bearing very low-density lipoprotein (LDL) particles. Hyperlipidemia in youth is a potentially atherogenic condition; therefore family history and fasting lipid levels are recommended for obese children. Intervention is indicated if total cholesterol, LDL cholesterol, or triglycerides are at or above the 95th percentile. Initial treatment begins with dietary measures to reduce calories and dietary cholesterol and recommendations to increase physical activity. Lipid-lowering medication is considered if behavioral modifications are unsuccessful. Obese youth may exhibit impaired glucose tolerance with insulin resistance and postprandial hyperinsulinemia. Impaired glucose tolerance is most common in children with a family history of type 2 diabetes mellitus. Insulin resistance is associated with acanthosis nigricans and menstrual irregularities. Insulin resistance is an independent risk factor for cardiovascular disease through effects on lipid metabolism and vascular changes. The development of type 2 diabetes poses further health risks, including renal, ophthalmologic, and vascular disease.

Metabolic syndrome, also called syndrome X, is a cluster of metabolic abnormalities that lead to cardiovascular disease and increased mortality (Box 298-2). Obesity, insulin resistance or hyperinsulinemia, dyslipidemia, and hypertension are the most commonly noted features. Adults with 3 of the following 5 findings meet criteria for the diagnosis of metabolic syndrome: elevated blood pressure, high triglyceride level, low HDL cholesterol level, high fasting glucose, and central obesity. Data from the National Health and Nutrition Examination Survey (2001 to 2006) estimates an overall prevalence in 12- to 19-year-olds of 8.1% (95% confidence interval [CI], 6.5% to 10.6%). The prevalence of metabolic syndrome may be as high as 30% in obese adolescents (12 to 19 years of age). The risk for metabolic syndrome increases with

### BOX 298-2 Metabolic Syndrome—Clinical Manifestations

#### OBESITY

- Excess body fat
- Increased visceral fat
- Central fat distribution

#### INSULIN RESISTANCE

- Decreased  $\beta$ -cell number
- Elevated fasting insulin levels
- Fasting insulin level  $>15$  mg/dL
- Peak insulin level  $>150$  mg/dL

#### DYSLIPIDEMIA

- Hypertriglyceridemia (very low-density lipoprotein)
- Low high-density lipoprotein
- Increased free fatty acids

#### HYPERTENSION

- Elevated systolic or diastolic blood pressure (or both)

#### GLUCOSE INTOLERANCE OR NON-INSULIN-DEPENDENT DIABETES MELLITUS

- Fasting plasma glucose level  $>126$  mg/dL
- 2-hour plasma glucose level  $>200$  mg/dL (oral glucose tolerance test)

the severity of adiposity (see Box 298-2). Increased odds for metabolic syndrome related to obesity are 66.9 (27.9, 160.4) in obese adolescent boys and 18.9 (6.3, 56.2) in obese adolescent girls. Obese black adolescents have lower risk for metabolic syndrome compared with non-Hispanic white and Hispanic adolescents.

Insulin resistance is thought to play a major role in the pathophysiologic mechanism of metabolic syndrome, with independent effects on lipid metabolism and cardiovascular health. Obese adolescents have higher plasma insulin levels than adolescents who are not obese. Overweight school children are more likely to have elevated total cholesterol, LDL cholesterol, triglycerides, and hyperinsulinemia than normal-weight children. Elevated insulin acts in the liver and in peripheral tissues to increase plasma triglyceride and LDL cholesterol levels. Controlling glucose metabolism reduces cardiovascular risk.

Obesity is associated with a chronic inflammatory state. Adipose tissue itself serves as a secretory organ, releasing peptides and cytokines into the circulation. Adiponectin, an anti-inflammatory peptide, is abundant in lean, insulin-sensitive individuals and is reduced in obese individuals. Low adiponectin levels correlate with a high BMI, and elevated levels of plasma triglycerides and free fatty acids. High adiponectin levels correlate with peripheral insulin sensitivity across age groups. In contrast, proinflammatory peptides, such as tumor necrosis factor- $\alpha$  and interleukin-6 (IL-6), are elevated in obese patients. Interleukin-6 stimulates the liver to produce C-reactive protein

(CRP), a marker of inflammation, and may be the link between obesity, subclinical inflammation, and coronary disease. Obese children have elevated CRP. Furthermore, a linear relationship exists between BMI and CRP and IL-6 levels. These markers have also been shown to correlate with other components of metabolic syndrome in children. Treatment of metabolic syndrome is aimed primarily at weight reduction and treating the component diagnoses: hypertension, diabetes, and hyperlipidemia. Evidence for short- and long-term efficacy of pharmacologic treatment of metabolic syndrome in youth remains sparse. Although studies of oral hypoglycemics (specifically metformin) in adolescents have demonstrated reductions in blood glucose, they have shown little effect on insulin resistance or lipid abnormalities. Although this medication may be helpful as an adjuvant therapy, behavioral and dietary modifications remain first line.

Other associated conditions include polycystic ovarian syndrome (PCOS) and nonalcoholic fatty liver disease (NAFLD) (Table 298-1). Polycystic ovarian syndrome is characterized by oligomenorrhea, insulin resistance, and hyperandrogenemia and may produce hirsutism or acne. Polycystic ovarian syndrome is associated with an increased risk for cardiovascular disease and infertility. Nonalcoholic fatty liver disease, increasingly recognized in obese youth, is most often asymptomatic and is characterized by mildly to moderately

elevated transaminase levels. Because NAFLD may progress to fibrosis and cirrhosis, screening in overweight youth is recommended. See Table 298-1 for conditions associated with obesity.

### MENTAL HEALTH COMORBIDITY

Mental health conditions often coexist with obesity. Nonetheless, the effects of obesity on child and adolescent mental health are still not well understood. During early childhood, body weight is not associated with self-esteem. However, as children approach adolescence, self-esteem is lower in overweight children than in normal-weight peers. Low self-esteem is more likely to be reported in obese 12- to 14-year-old girls compared with nonobese (odds ratio [OR], 3.5; 95% CI, 1.3 to 9.2). They also reported poor school and social functioning (OR, 2.3; 95% CI, 1.2–4.7). Adolescent girls who are concerned about their weight also report more depressive symptoms. Furthermore, depressed adolescents are at increased risk for developing persistent obesity. Otherwise, overweight youth are likely to report physical but not emotional problems, even though some studies show that they may be socially excluded. When caring for overweight and obese children, assessing affect and mental health status is advisable.

Based on a recent, large representative US study of 10- to 17-year-old youths, obese individuals showed increased odds for internalizing problems (adjusted

**Table 298-1** Medical Conditions Associated With Obesity

CONDITION	DISEASE	DESCRIPTION
Cardiovascular	Hypertension Dyslipidemia	SBP >95th percentile for sex, age, and height LDL >130 mmol/L HDL <40 mmol/L Total cholesterol >200 mmol/L Atherosclerosis begins during childhood
	Cardiovascular disease	
Endocrine	Type 2 diabetes mellitus Insulin resistance Polycystic ovarian syndrome	FBG >110 mg/dL Increased serum insulin levels Menstrual irregularities, hirsutism, acne, insulin resistance, hyperandrogenemia
	Metabolic syndrome	Obesity, hypertension, dyslipidemia, insulin resistance
Gastrointestinal	Nonalcoholic fatty liver disease	Increased transaminases; may progress to fibrosis or cirrhosis
	Gallbladder disease	May account for 50% of cases in adolescents
Pulmonary	Obstructive sleep apnea	Snoring, apnea, restless sleep, behavioral problems
Orthopedic	Slipped capital femoral epiphysis	Hip or knee pain, decreased mobility of hip
	Blount disease (tibia vara)	Severe bowing of the tibia
	Osteoarthritis	May present in adolescence
Neurologic	Pseudotumor cerebri	Headaches, vision changes, papilledema
Psychiatric	Anxiety Low self-esteem	Sometimes difficult to assess whether the depression or low self-esteem is the cause of the weight gain or if the weight gain is the cause of the depression
	Depression	
Oncologic	Endometrial cancer	Increased prevalence with adult obesity
	Breast cancer	Increased prevalence with adult obesity
	Colon cancer	Increased prevalence with adult obesity

FBG, Fasting blood glucose; HDL, high-density lipoprotein; LDL, low-density lipoprotein; SBP, systolic blood pressure.

odds ratio [AOR], 1.59, 95% CI, 1.04–2.45), externalizing problems (AOR, 1.33; 95% CI, 1.07–1.65), grade repetition (AOR, 1.57; 95% CI, 1.24–1.99), school problems, and missed school days. In addition, attention-deficit/hyperactivity disorder, conduct disorder, depression, learning disability, developmental delay, bone/joint/muscle problems, asthma, allergies, headaches, and ear infections were all more common in obese children and adolescents.

## COSTS

The current epidemic of obesity poses a significant threat to health care systems already struggling with escalating costs. The US Surgeon General predicted that the costs related to obesity will overtake those of tobacco. Obese adults have higher health care costs compared with normal-weight adults. Excess health care costs for obese individuals are 58% higher than those of smokers. Furthermore, medication expenses are 77% higher for obese individuals compared with those who are not obese. Obesity is associated with having more medical diagnoses and medications, leading to increased medical costs equivalent to 20 years of aging. These figures do not attempt to capture the cost of psychological morbidity.

## DIFFERENTIAL DIAGNOSIS

Primary medical causes of obesity are rare. Endocrine and genetic causes of obesity often cause short stature or cognitive impairment. Children who consume excess calories are likely to experience accelerated linear growth. Therefore, short stature in an overweight child warrants further evaluation. Similarly, syndromes associated with intellectual disability and obesity should be considered in obese children with

developmental delay. Table 298-2 lists endocrine and genetic causes of obesity.

## LABORATORY EVALUATION

Obesity is diagnosed by measuring height and weight and calculating BMI. The rate of obesity identification in pediatric practices is low. Electronic medical record systems with automated plotting of BMI percentiles and prompts for elevated BMI have the potential to improve identification. Brief provider training has also been shown to improve provider identification of BMI and the performance of recommended screening and counseling.

Published guidance for lipid screening by the American Academy of Pediatrics supports fasting lipid screening for children and adolescents whose BMI is at or above the 85th percentile. Lipid screening is also recommended for those with a family history of dyslipidemia, cigarette smokers, and those with diabetes mellitus. In 2011, the National Institute for Heart, Lung and Blood published a recommendation for universal pediatric lipid screening beginning with a nonfasting lipid screen. There is considerable ongoing research, which is expected to result in evidence that will clarify the most effective method for identifying children and adolescents with hyperlipidemia.

The American Diabetes Association recommends a fasting glucose test for children whose BMI is at or above the 85th percentile and for those whose BMI is between the 85th and the 95th percentile if they have a family history of diabetes mellitus or obesity or signs of insulin resistance, including acanthosis nigricans, PCOS, or hirsutism (see Box 298-3). (See Chapter 241, Diabetes Mellitus.) Hemoglobin A1c is sometimes used

**Table 298-2** Endocrine and Genetic Causes of Obesity

DIAGNOSIS	ASSOCIATED SYMPTOM	SIGNS AND SYMPTOMS	TESTING
Hypothyroidism	Short stature	Weight gain, fatigue, constipation, cold intolerance, myxedema	TSH, FT4
Cushing syndrome	Short stature	Central obesity, hirsutism, moon face, plethora, hypertension	Dexamethasone suppression test
Pseudohypoparathyroidism	Short stature	Short metacarpals, subcutaneous calcifications, dysmorphic facies, intellectual disability, hypocalcemia, hyperphosphatemia	Urine cAMP after synthetic PTH infusion
Growth hormone deficiency	Short stature	Fatigue	Evoked GH response, IGF-1
Down syndrome	Short stature	Dysmorphic facies, intellectual disability	Karyotype
Turner syndrome	Short stature	Web neck	Karyotype
Prader-Willi syndrome	Cognitive impairment	Hypogonadism, small hands and feet	FISH <i>15q11</i> microdeletion (70% of cases)
Bardet-Biedl syndrome	Cognitive impairment	Retinitis pigmentosa, renal abnormalities, polydactyly, hypogonadism	<i>BBS1</i> gene
Biemond syndrome	Cognitive impairment	Iris coloboma, hypogonadism, polydactyly	Clinical
Alström syndrome	Cognitive impairment	Retinitis pigmentosa, diabetes mellitus, and hearing loss	<i>ALMS1</i> gene

cAMP, cyclic adenosine monophosphate; FISH, fluorescent in situ hybridization; FT4, free thyroxine; GH, growth hormone; IGF, insulin-like growth factor; PTH, parathyroid hormone; TSH, thyroid-stimulating hormone.

to screen children who are unable to comply with fast-ing before the laboratory test. Insulin levels are not currently recommended for evaluating obesity because they can be elevated, low, or normal at the time of pre-sentation of type 2 diabetes.

Baseline liver function tests should be checked for obese children and adolescents. Liver function tests should also be performed before pharmacologic man-agement for type 2 diabetes or surgical intervention for obesity. Other laboratory studies are ordered only as indicated by history or physical examination (Table 298-3; see also Box 298-3).

**BOX 298-3 Criteria for Screening High-Risk Children for Diabetes**

- Overweight (body mass index >85th percentile for age and sex), **AND** any 2 risk factors:
- Family history of type 2 diabetes in a first- or second-degree relative
  - High-risk race or ethnicity (Native American, African American, Latino, Asian American, and Pacific Islander)
  - Signs of insulin resistance or associated conditions:
    - Acanthosis nigricans
    - Hypertension
    - Dyslipidemia
    - Polycystic ovarian syndrome
    - Small for gestational age
  - Maternal history of diabetes or gestational diabetes
- Age to initiate screening:
- 10 years, **OR**
  - Onset of puberty if younger than 10 years
- Frequency: every 3 years
- Preferred screening test: plasma glucose after an 8-hour fast

**PRIMARY PREVENTION**

Preventing childhood obesity is crucial to public health and requires the concerted efforts of public health of-ficials and multiple government agencies, schools, and health care systems.

Pediatricians and other physicians who care for children have the opportunity to educate families about the importance of healthy nutrition and physical activity from the earliest years. Much confusion exists about good nutrition. Healthful nutrition begins with breastfeeding, which is associated with a lower childhood obesity risk. Exclusive breastfeeding is rec-ommended for 6 months by the World Health Organi-zation along with timely introduction of adequate and safe complementary foods. The American Academy of Pediatrics also recommends introduction of comple-mentary foods at around 6 months. Infants should be provided with a range of flavors so that they become accustomed to the taste of healthy foods, including vegetables (see Chapter 36, Healthy Nutrition: Infants). Consideration of nutrient quality and caloric content is the basis of a healthy diet. Calorie-laden foods with little nutritional value can be offered for occasional treats. Families can begin by planning meals and snacks based on fruits, vegetables, and grains. Healthy diets can include meat and dairy products, supplying fewer calories than fruits, vegetables, and grains. Milk provides important nutrients during childhood, and low-fat milk is recommended for most children after age 2 years. Children should be encouraged to drink water to quench thirst, reserving highly sug-ared beverages for occasional treats. Fruit juice should be consumed in moderation (1 per day, <4 ounces). Fruit and small portions of yogurt, cookies made with oatmeal, occasional puddings made with milk and eggs, and ice cream are satisfying compo-nents of a healthy diet. Using less saturated fat is sug-gested for cardiovascular health. Attention to portion size is important. Children learn food preferences early in life and may also develop habits associated with appetite and satiety.

**Table 298-3 Laboratory Testing as Indicated by Screening Guidelines, History, or Physical Examination**

TEST	INDICATIONS
Thyroid function tests	When symptoms of hypothyroidism are present
Plain-film radiographs	For deformity, hip or knee pain (SCFE or Blount disease)
Head computed tomographic scan, lumbar puncture	Headache, visual changes, papilledema (pseudotumor cerebri)
LH, FSH, total and free testosterone; consider pelvic ultrasound	Menstrual irregularity, acne, hirsutism (PCOS)
Genetic consultation, karyotype	Short stature, dysmorphic features, cognitive impairment
Lipid panel	Ages 2–8 years if family history of dyslipidemia or early cardiovascular disease (<55 years in males, <65 years in females) or if child has diabetes, hyperten-sion, BMI >95th percentile, smokes cigarettes, or has moderate- to high-risk medical condition (ie, renal failure, hypothyroidism, and liver failure). Ages 9–11 years: Universal screening for all children <sup>a</sup> Ages 17–21 years: Universal screening for all children/young adults

BMI, body mass index; FSH, follicle-stimulating hormone; LH, luteinizing hormone; PCOS, polycystic ovary syndrome; SCFE, slipped capital femoral epiphysis.  
<sup>a</sup>Current recommendation at the time of publication.

Physical activity habits similarly begin early in life. Children whose parents are physically active are more likely to be physically active themselves. Physicians can encourage families to consider planning opportunities for physical activity as a parental responsibility. Children should engage in at least 60 minutes of physical activity on most, preferably all, days of the week. Children who participate in organized sports should be encouraged to be physically active when there are no organized activities. It is unnecessary to rely on organized sports to meet all physical activity recommendations. In addition to aerobic activities, older children and adolescents may benefit from strength training. Overweight children often find this form of physical activity rewarding because strength training does not require aerobic endurance or agility. Overweight children can therefore benefit psychologically and physically from strength training. Increasing physical activity should be accompanied by decreasing sedentary activities. Limiting television and other recreational screen time to less than 2 hours per day is recommended. The American Academy of Pediatrics recommends no television for children younger than 2 years. Parents should strive to be role models for their children for dietary and physical activity habits. Child health professionals can begin to talk to parents about healthy nutrition and activity during the first year of life. These themes can be revisited at annual health care maintenance visits along with BMI monitoring.

Body mass index should be calculated and plotted at each health care maintenance visit. Computerized systems that automatically calculate and plot these percentiles make this feasible. Tracking growth trajectories and explaining these patterns to parents is an essential component of primary prevention. Children with increasing BMI percentiles may be at risk for developing obesity. Health care professionals can help families evaluate nutritional and activity patterns and make adjustments. Child health professionals need to identify parental obesity as a risk factor for the child. Given that early childhood obesity often resolves, optimism is warranted in the early years. By adolescence, nutritional and activity patterns are more difficult to change, and families have less influence. Strategies to engage the parent in preventive efforts are needed. Obesity remains an emotionally charged issue, creating more difficulties for the family and the pediatrician than more purely medical problems.

## INTERVENTION—PREVENTION OF SECONDARY COMORBIDITY

Preventing secondary comorbidity and disability is the principal goal in treating overweight children and adolescents. The primary care physician is faced with the challenge of educating the child and family about lifetime health risks imparted by excess body weight. These risks may seem abstract to the family because they are unlikely to occur for many years. Obesity should be approached as a chronic condition that requires permanent lifestyle change to achieve optimal body weight. Recent work with obese children and their families supports the utility of using the stages of change model for assessment of readiness to change

followed by motivational interviewing (see Chapter 46, Effective Communication Strategies.). Prescribing a treatment plan without engaging the child and family can lead to frustration and feelings of futility, impairing future attempts at weight control. Enhancing the therapeutic relationship can begin with a question to the parent, “Have you ever struggled with your weight?” The answer to this question will reveal a great deal about the family’s perception of body weight as an indicator of health and well-being and the parent’s empathy for the child. Readiness to change can be assessed by asking the child and parent 3 questions:

- How concerned are you about your weight (your child’s weight)?
- Do you think that you can improve your body fitness (your child’s body fitness)?
- Do you think that your family can change eating and physical activity patterns?

If the child is seriously overweight (above the 99th percentile) or has medical complications, referral to a behavioral health specialist may be necessary for the family to progress to a state of readiness to change.

When the child and family are ready to begin a treatment plan, the physician should assist them in setting realistic goals (Box 298-4). Weight maintenance rather than weight loss is usually the first step for growing youth. The objective is to decrease the rate of weight gain and allow the child to achieve a healthier body mass (Box 298-5). Learning healthy eating and activity habits improves the child’s health over time (Box 298-6 and Box 298-7). Focusing on health and healthy behavior changes allows for gradual and long-term change. Fad diets and very low-calorie regimens are not recommended for children because these diets cannot be maintained. Children who possess an acute comorbidity such as sleep apnea may be managed medically (usually in an inpatient treatment program) on a very low-calorie diet. Recommendations for weight maintenance or weight loss are based on the level of overweight, age, and existence of complications (Figure 298-1). Setting goals for weight

### BOX 298-4 Role of the Pediatrician

- Intervene early.
- Assess family’s readiness to change.
- Educate family about medical complications of obesity.
- Involve family and caregivers in the treatment program.
- Aim for permanent dietary and activity change.
- Avoid short-term diets or exercise programs aimed at rapid weight loss.
- Teach family to monitor eating and activity.
- Assist family in making small, gradual changes.
- Encourage and empathize.
- Avoid criticism.
- Refer obese children to a family-based behavioral obesity treatment program.

**BOX 298-5 Parenting Skills for Weight Loss**

- Find reasons to praise child's behavior.
- Set clear guidelines about food.
- Avoid using food as a reward.
- Establish daily family meal, family snack times, and physically active family time.
- Determine what food is offered and when.
- Allow child to decide whether to eat.
- Offer only healthy options.
- Remove temptations (snack food in home).
- Walk instead of drive, take the stairs; decrease television-viewing time.
- Be a role model in diet and physical activity.
- Be consistent.

**BOX 298-6 Dietary Modifications**

- Drink water, sugar-free beverages, or milk with no more than 1% fat.
- Use cooking spray instead of frying.
- Make cut-up fruits and vegetables accessible.
- Limit seconds to fruits and vegetables.
- Serve appropriate portions of meat (size of your palm) and starch (½ cup).
- Review school lunch menu with child to pick healthy options.
- Pack lunch with 4 oz lean meat, whole grain bread, fruit or vegetable, and milk.
- Limit restaurant dining to once per week or less.
- Limit fast food to rarely.
- Eat meals together, and turn off the television while eating.
- Schedule at least 20 minutes for each meal. Eating slowly helps to avoid overeating.
- Eat regular meals. Skipping meals can lead to overeating.
- Remove snack foods, chips, cookies, and desserts from the house.
- Allow occasional treats.
- Make salads with vegetables, not eggs, meat, bacon, or cheese.
- Toss family salad to decrease amount of dressing.

maintenance or weight loss may be based on a child's BMI, age, and complications (see Figure 298-1 and Box 298-4, Box 298-5, Box 298-6, and Box 298-7).

Family-based behavioral treatment programs are evidence-based strategies for treating childhood obesity. These programs involve training the parent in stimulus control and behavioral reinforcement techniques designed to promote child behaviors to facilitate weight loss. In addition, parents are encouraged

**BOX 298-7 Increasing Physical Activity**

- Limit television and video games to no more than 1 to 2 hours per day.
- Engage in active family activities: Ride a bike, walk after dinner, swim, go to zoo or museum.
- Dance to your favorite music.
- Walk with a friend rather than talking on the telephone.
- Walk while you talk on the telephone.
- Engage in team sports.
- Take classes—dance, martial arts, or swimming.
- Strategies for toddlers and preschool-aged children:
  - Engage in outdoor play every day.
  - Engage in active indoor play, soft balls, jumping, or bouncy balls.
  - Buy active toys rather than computer games or videos.

to use an authoritative parenting style and to model healthy behaviors. Involvement in these treatment programs is often associated with weight loss for the parent as well as for the child. For school-aged children, parent-only treatment has been shown to be effective.

To date there is no evidence that pharmacologic agents for weight loss are safe and effective for children. Bariatric surgery may be considered in severely overweight adolescents (BMI >40) with significant medical complications and nearly complete skeletal maturity. Generally it would not be considered without a 6-month trial of dietary and exercise modifications with inadequate improvement. After evaluation by a multidisciplinary team, surgery can be performed by surgeons who are experienced in gastric bypass surgery. A major dilemma in the care of adolescents is how to give informed consent or assent about the consequences of both obesity and the alternative of bariatric surgery. The procedure will change their ability to eat and may have unforeseen long-term consequences. On the other hand, obesity may threaten their lives.

## Chapter 299

# OBSTRUCTIVE UROPATHY AND VESICoureTERAL REFLUX

Hiep T. Nguyen, MD

## OBSTRUCTIVE UROPATHY

Obstructive uropathy is a collective spectrum of biologic changes in the kidney that can result from an impairment of urinary flow at any point in the urinary tract. These changes include proliferation and myofibroblastic transformation of interstitial fibroblasts, expansion of extracellular matrix, loss of renal tubular cells, and decreased numbers of nephrons. They may

have a wide range of effects on the kidney, from sodium wasting, hyperkalemic acidosis, and nephrogenic diabetes insipidus to renal insufficiency or failure. Their effect on renal growth, development, and function depends on the timing, severity, and duration of the urinary obstruction. Obstruction that occurs early during renal development will lead to dysplasia and an arrest of renal development with the persistence of fetal architecture. In contrast, obstruction at the later stages of development may result only in dilatation of the collecting system (ie, hydronephrosis). Complete obstruction, such as from urethral atresia, has more detrimental effects on renal development and function than partial obstruction.

Children with obstructive uropathy usually exhibit urinary tract infections (UTIs). Less common modes of presentation include abdominal mass, hematuria, urinary stone, poor urinary stream, incontinence, failure to thrive, and renal insufficiency or failure. With the advent of routine second-trimester ultrasound (US) screening, most cases of obstructive uropathy are now being detected prenatally. The incidence of prenatal hydronephrosis ranges from 1:100 to 1:500, representing one-half of all abnormalities detected by prenatal US. However, clinical experience has shown that the presence of hydronephrosis does not necessarily indicate the presence of urinary obstruction. The difficulty lies in determining which patients have dilatation that has the potential for compromising renal function. The ability to diagnose clinically important obstruction properly is essential because obstructive uropathy is the leading cause of renal failure in children younger than 2 years and accounts for 17% of the cases of kidney transplants in children.

## DIFFERENTIAL DIAGNOSIS

Obstruction can develop at various locations, resulting in dilatation of the urinary tract (ie, hydronephrosis). The differential diagnosis for hydronephrosis is listed in Box 299-1. Ureteropelvic junction (UPJ) obstruction occurs when an impairment of urine flow occurs from the renal pelvis into the proximal ureter, causing progressive dilatation of the renal pelvis and calyces and potential renal injury. Its anatomic basis is from either an intrinsic or an extrinsic cause. The intrinsic obstruction results from luminal narrowing of the UPJ, with or without kinking, and is usually characterized by excessive connective tissue and decreased smooth muscle content in the ureteral wall (Figure 299-1, A). In contrast, extrinsic obstruction is caused by compression of the ureter by anomalous (eg, lower pole) renal vasculature (Figure 299-1, B). This type of UPJ obstruction is more commonly found in older children and adults. UPJ obstruction is the most common cause of obstructive uropathy in children and is second only to transient, physiologic non-pathologic hydronephrosis as the most common cause of antenatal hydronephrosis (Table 299-1). The incidence of UPJ obstruction is estimated to be 1 in 1,500, with a male-to-female ratio of 2:1. The left side is more commonly affected than the right side (left:right ratio of 1.5:1). Bilateral UPJ obstruction is present in 10% to 40% of cases of neonatal hydronephrosis.

**BOX 299-1 Differential Diagnosis for Hydronephrosis**

- UNILATERAL<sup>a</sup>**
- Ureteropelvic junction obstruction
  - Ureterovesical junction obstruction
  - Ureterocele
  - Ectopic ureter
  - Polycystic kidney disease
  - Extrarenal pelvis
  - Unilateral vesicoureteral reflux
  - Transient physiologic-nonpathologic

- BILATERAL**
- Posterior urethral valves
  - Urethral atresia
  - Prune belly syndrome
  - Megacystis-megaureter syndrome
  - Vesicoureteral reflux
  - Polycystic kidney disease

- UNCOMMON CAUSES**
- Megacalycosis
  - Renal cyst
  - Urachal cyst
  - Ovarian cyst
  - Hydrocolpos
  - Sacrococcygeal teratoma
  - Bowel duplication
  - Duodenal atresia
  - Anterior meningocele

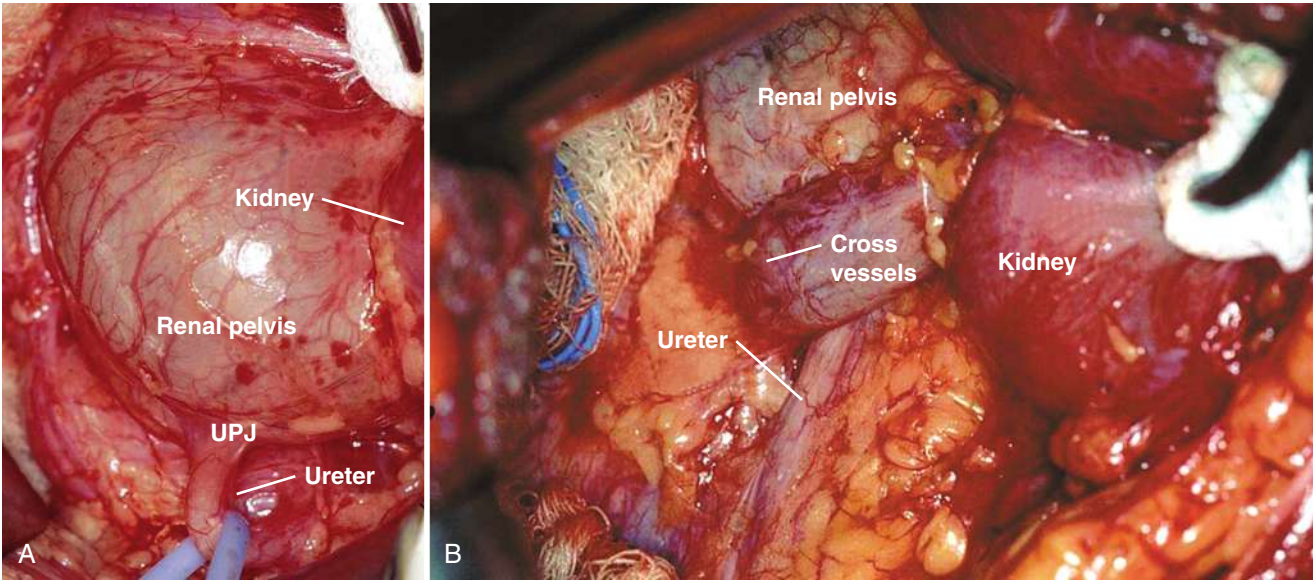

<sup>a</sup>Can also be bilateral

Ureterovesical junction (UVJ) obstruction, also referred to as *obstructed megaureter*, is an impairment of urinary flow from the distal ureter into the bladder, resulting in dilatation of the entire collecting system from the distal ureter to calyces. UVJ obstruction may be primary or secondary. Primary obstruction is caused by a deficiency of smooth muscle in the intravesical ureter, resulting in an adynamic distal segment that impedes normal peristalsis of urine through the ureter (Figure 299-2). Secondary obstruction results from compression of the ureter by a thick bladder wall in pathologic states such as posterior urethral valves (PUV) or neurogenic bladder. Clinically significant UVJ obstruction accounts for approximately 8% of children who had symptoms such as infection, hematuria, or pain and who were found to have hydroureteronephrosis by imaging studies. However, it accounts for 23% of newborns with prenatally diagnosed hydronephrosis and is the third most common

**Table 299-1 Etiology of Prenatal Hydronephrosis**

ETIOLOGY	REPORTED INCIDENCE
Transient physiologic-nonpathologic	50%–70%
Ureteropelvic junction obstruction	10%–40%
Vesicoureteral reflux	10%–30%
Ureterovesical junction obstruction	5%–20%
Multicystic dysplastic kidney	2%–5%
Posterior urethral valves	1%–5%
Other*	1%–2%

\*Other causes include ureterocele, ectopic ureter, duplex system, urethral atresia, prune belly, polycystic kidney disease, and renal cysts.

**Figure 299-1** A, Intrinsic ureteropelvic junction obstruction. B, Extrinsic ureteropelvic junction obstruction cause by crossing vessels.

**Figure 299-2** Primary ureterovesical junction obstruction.

cause of prenatal hydronephrosis, preceded by transient, physiologic nonpathologic hydronephrosis and UPJ obstruction. As with UPJ obstruction, UVJ obstruction is more common in boys and occurs more often on the left side. It occurs bilaterally in 10% of cases, and contralateral renal anomalies (eg, renal agenesis, multicystic dysplastic kidney) are observed in approximately 9% of patients with UVJ obstruction.

Lower urinary tract obstructions are a less common cause of obstructive uropathy. The most common cause of intravesical obstruction is PUVs. One hypothesis suggests that the terminal ends of the wolffian ducts misintegrate and are abnormally integrated into the urethral wall. This action results in obliquely oriented ridges that act as a one-way valve, impeding urine flow from the bladder (Figure 299-3). The incidence of PUV is estimated to be 1 in 5,000 to 1 in 8,000 boys.

Other notable but uncommon causes of obstructive uropathy include ureterocele and ectopic ureter. A ureterocele is a cystic dilatation of the intravesical submucosal ureter, usually associated with a stenotic orifice that impairs urinary flow into the bladder (Figure 299-4). The cause of the ureterocele remains unknown, but investigators hypothesize that it results either from an incomplete breakdown of the ureteral (Chwalla) membrane present at the time of the ureteral bud arising from the mesonephric duct or from a delay in the establishment of the lumen of the ureteral bud. The incidence of ureteroceles is approximately 1 in 500 to 1 in 4,000 children. Ureteroceles are found more commonly in girls (female:male ratio of 7:1) and are bilateral in 10% of cases. In 80% of cases, they are associated with the upper pole ureter of a duplex kidney. An ectopic ureter is one that inserts into an abnormal site (ie, a site other than the bladder trigone), which results from a ureteral bud with an abnormally high origin from the mesonephric duct. In boys, the possible insertion sites for the ectopic ureter are always above the urinary sphincter, whereas, in girls, they can be above or below the sphincter. Consequently, ectopic ureters in boys are often obstructive, whereas those in girls may not be. The incidence of ectopic ureter is approximately 1 in

**Figure 299-3** Voiding cystourethrogram demonstrating posterior urethral valves as a cause for bladder outlet obstruction.

**Figure 299-4** Ureterocele.

1,900. Similar to ureteroceles, only 15% of ectopic ureters occur in boys, and in 80% of cases, the ectopic ureter is associated with the upper pole of a duplex kidney. It occurs bilaterally in approximately 10% of cases. Hypoplasia or dysplasia of the associated renal unit is commonly associated with the ectopic ureter.

**Figure 299-5** Ultrasound demonstrating dilated ureter seen behind bladder caused by ureterocele.

## RADIOLOGIC EVALUATION

Before the advent of routine maternal US, children with obstructive uropathy primarily displayed symptoms such as febrile UTI, abdominal mass, pyuria, pain, hematuria, and gastrointestinal symptoms. Less common presenting symptoms included failure to thrive, anemia, sudden onset of hypertension, and renal insufficiency or failure.

A renal and bladder US should be performed first. In children with obstructive uropathy, hydronephrosis is almost always present. However, its presence should not be interpreted as a sign of clinically significant obstruction, because US cannot adequately assess renal function and drainage of the upper urinary tract. Although increased echogenicity and marked parenchymal thinning may portend poor renal function, these findings are not sensitive or specific. Aside from the presence of hydronephrosis, the US may help differentiate the cause of obstructive uropathy. The presence of a dilated ureter on US suggests that the level of obstruction occurs distal to the UPJ, such as from UVJ obstruction, ectopic ureter, ureterocele, or PUV (Figure 299-5). A ureterocele can be visualized as a cystic mass inside the bladder, whereas the presence of a thick wall bladder and a dilated posterior urethra suggests the diagnosis of PUV.

To identify the cause of the obstructive uropathy and to assess renal function accurately, additional imaging studies are often required. A voiding cystourethrogram (VCUG) will identify the presence of vesicoureteral reflux (VUR), a condition that may cause hydronephrosis itself but is found in association with other diagnoses of obstructive uropathy, including UPJ obstruction, ureterocele, and PUV. In addition, a VCUG will help delineate bladder and urethral anomalies such as ureterocele and PUV, respectively. Renal function can be assessed with radionuclide renography.  $^{99m}\text{Tc}$  dimercaptosuccinic acid (DMSA) provides the most accurate assessment of

renal function and the presence of renal scarring.  $^{99m}\text{Tc}$  diethylenetriaminepentaacetic acid (DTPA) and  $^{99m}\text{Tc}$  mercuroacetyltriglycine diuretic renography are less accurate in determining renal function but do provide an assessment of drainage and a quantitative measurement of the degree of obstruction (ie,  $t_{1/2}$ , the time required to achieve 50% clearance of pyelocaliceal activity in the region of interest). However, debate continues about the accuracy of using  $t_{1/2}$  in diagnosing obstruction. Diuretic renography should only be obtained in children at least 2 months of age (because of tubular function maturation) who have moderate or severe hydronephrosis; in these cases, the studies are the most informative. Intravenous pyelogram is an alternative study that can provide assessment of both renal function and anatomy. However, its use in children is limited because of the amount of radiation exposure and the presence of bowel gas, which interferes with the visualization of the urinary tract.

With the advent of routine prenatal US, many children with obstructive uropathy are now detected in utero with hydronephrosis before they develop symptoms. However, not all children with prenatal hydronephrosis have obstructive uropathy; most have transient or physiologic hydronephrosis that often resolves during pregnancy or after birth and do not have any clinical sequelae. Consequently, not all children with prenatal hydronephrosis require extensive radiologic evaluation. If the hydronephrosis persists during pregnancy, then a postnatal US after 48 hours is indicated. In severe cases, such as bilateral moderate to severe hydronephrosis, solitary kidney, oligohydramnios, or giant hydronephrosis, the postnatal US should be done sooner. Because patients with high-grade VUR can have normal US without any hydronephrosis, whether patients with prenatal hydronephrosis should undergo a VCUG regardless the degree of hydronephrosis is a point of debate; the incidence of VUR in children with mild prenatal hydronephrosis was only 4.4% and was 14% in the moderate group. Consequently, a VCUG in patients with mild prenatal hydronephrosis is not needed. However, a VCUG may be indicated if a dilated ureter is seen on US or other clinically significant obstructive uropathies, such as UPJ obstruction or PUV, are suspected. Additional radiographic evaluation with diuretic renography or intravenous pyelogram is limited to specific cases with moderate to severe hydronephrosis, marked parenchymal thinning, or increased echogenicity noted on US. When the degree of prenatal hydronephrosis is not known, a postnatal US should be obtained. The moderate and severe degrees of postnatal hydronephrosis are correlated with increased incidence of obstructive uropathy.

## MANAGEMENT

The goals in the treatment of obstructive uropathy are to preserve renal function and to prevent the development of associated complications such as UTI, pain, and stone formation. Although in some cases the hydronephrosis can spontaneously resolve as the child grows, in other cases it persists, leading to progressive renal compromise. Consequently, the primary

care physician must determine which patients will benefit from surgical intervention and which should be observed, with the expectation that hydronephrosis will resolve without compromising renal function. In many instances, making this determination is difficult, leading to controversies in the management of obstructive uropathy.

In the management of UPJ obstruction, patients with a severely dilated renal pelvis (anteroposterior >2 cm on US), decreased renal function (relative renal function <40%), and marked obstructed pattern on renography ( $t_{1/2}$  >20 minutes) should undergo surgical correction. Surgical correction is accomplished by either removing the stenotic or adynamic UPJ or transposing the ureter anterior to the lower pole-crossing vessels. Other indications for surgery include UTI, renal colic, or pulmonary compromise from giant hydronephrosis. Patients with moderate to severe hydronephrosis, but preserved renal function, may be managed without surgery. The hydronephrosis will resolve in many cases, although it may take several years. In some cases, declining renal function may occur, necessitating surgery. However, in most cases, renal function is recovered after surgery, suggesting that the risk to the obstructed kidney from conservative management is small.

In the management of UVJ obstruction, removal of the distal adynamic segment of the ureter with or without ureteral tapering is indicated in patients with symptoms who seek care for UTI, pain, or nausea and vomiting. In patients who are asymptomatic (ie, diagnosed by evaluation of prenatal hydronephrosis), observation and prophylactic antibiotics have been shown to be safe, allowing for spontaneous regression of the obstruction without a compromise in renal function and minimizing the risk of UTI. Most symptoms will resolve spontaneously. Occasionally, infants with UVJ obstruction diagnosed in the evaluation for prenatal hydronephrosis have greatly decreased renal function at the onset. In these patients, surgical correction is indicated. Although renal function after the procedure is preserved, it is never normalized.

Lower urinary tract obstruction, such as from PUV, usually requires more urgent intervention because both kidneys are at risk. In patients with suspected PUV, catheter drainage is needed until the diagnosis is confirmed and surgical correction can be performed. Stabilization of the patient's pulmonary status (particularly in newborns diagnosed in utero with oligohydramnios), correction of associated metabolic abnormalities, and treatment of UTI should be performed before any surgical intervention. In most patients, endoscopic fulguration of the PUV relieves the bladder outlet obstruction. However, a vesicostomy or alternative treatment, such as ablation with a Fogarty balloon, may be required in very small or premature infants when an endoscopic procedure cannot be performed because of the size of the instruments.

Long-term therapy is directed toward the identification and treatment of associated metabolic abnormalities and bladder dysfunction. After the PUV are treated, the patients may develop postobstructive diuresis with urine output as high as 15 mL/kg/hour; careful attention to the patient's fluid balance is,

therefore, essential after the relief of distal obstruction. Renal insufficiency and failure can occur in up to 50% of patients with PUV. Children with PUV who have a nadir creatinine level of more than 0.8 mg/dL at 1 year of age are at high risk of developing renal insufficiency or failure. Not uncommonly, children with PUV and renal insufficiency lack the ability to concentrate their urine to a specific gravity of more than 1.015, leading to excessive fluid loss. These patients may also develop renal salt wasting and metabolic acidosis with hyperkalemia. In these patients, minor gastrointestinal illness can result in severe dehydration and cardiovascular compromise. In addition to the associated metabolic complications, bladder dysfunction is often associated with PUV despite adequate relief of the obstruction. VUR occurs in approximately 30% to 75% of children with PUV. Antibiotic prophylaxis is indicated in children with PUV and VUR, because improvement in the grade of the reflux occurs with time in most patients. The valve bladder is often poorly compliant and functionally lacks normal sensation. Consequently, many patients with PUV are able to hold large urine volumes at high intravesical pressures. With time, this circumstance can lead to increased upper tract dilatation and pressure and progressive renal compromise. Early treatment of the valve bladder with anticholinergic medications, intermittent catheterization, and nighttime drainage seem to reduce the incidence of bladder and renal dysfunction.

In the management of ureterocele and ectopic ureter, surgical correction is usually needed. As in the management of the other types of obstructive uropathy, urgent surgical correction is indicated in patients who are symptomatic. In children diagnosed during the evaluation for prenatal hydronephrosis, the type and timing of surgical correction are controversial. Long-term follow-up is needed to evaluate renal function and to look for recurrent obstruction. Hypertension and proteinuria can develop in patients with renal insufficiency or dysplasia. Consequently, yearly blood pressure and urinalysis are indicated in all patients with obstructive uropathy.

Fetal intervention for obstructive uropathy is indicated only in specific cases. The goal of fetal intervention is to prevent pulmonary hypoplasia and to preserve renal function. Open fetal surgery, percutaneous vesicoamniotic shunt placement, and fetoscopic surgery have been used with varying success in the treatment of obstructive uropathy such as PUV. Because of the inherent risks of the procedure for the fetus and the mother, fetal intervention should be considered only in cases in which pulmonary or renal dysfunction can be identified and cases in which the treatment of obstructive uropathy will improve pulmonary and renal function. In most cases, obstruction occurs unilaterally; thus, overall renal function and, hence, pulmonary function are normal, and fetal intervention is not indicated. In cases of lower urinary tract obstruction or bilateral obstruction, assessment of renal function should be performed to determine whether fetal intervention is warranted. Serial measurements of urine electrolytes are helpful in assessing fetal renal function. Healthy fetal kidneys produce hypotonic urine,

whereas those that are impaired produce isotonic urine. Consequently, increased urine sodium, chloride, and osmolality suggest the presence of renal damage or dysplasia. Favorable prognosis for good renal function is associated with sodium concentration less than 100 mEq/L, chloride less than 90 mEq/L, osmolality less than 210 mOsm/kg, and  $\beta_2$ -microglobulin less than 508 mmol/L. Analysis of the urine obtained from serial bladder taps at 48- to 72-hour intervals better reflects renal function because the initial sample may be stagnant.

The success of fetal intervention has been variable. Typically, normal amniotic fluid volume is restored, and an associated improvement in lung development is seen. Unfortunately, renal outcome is not significantly improved. A high complication rate is associated with fetal intervention, including premature labor, inadequate drainage or migration of the shunt, perforation of fetal bowel or bladder, chorioamnionitis, iatrogenic gastroschisis, and bleeding. Currently, fetal intervention is primarily reserved for cases in which severe oligohydramnios occurs without associated renal dysplasia, poor renal function, or associated chromosomal anomalies.

## VESICoureTERAL REFLEX

### Definition and Epidemiologic Features

Vesicoureteral reflux occurs when urine in the bladder flows in a retrograde manner into the upper urinary tracts. Under normal conditions, the ureter passes obliquely through the bladder wall with an appropriate submucosal tunnel length and opens onto the trigone of the bladder in a correct location. VUR is prevented by the compression of the intravesical ureter against the bladder wall, which can be accomplished only with the appropriate UVJ anatomy. VUR may result from maldevelopment or delayed maturity of the UVJ (primary reflux) or from distortion of the UVJ by changes in the bladder that are caused by other conditions, such as PUV or neurogenic bladder (secondary reflux). Researchers have long recognized an association between the presence of VUR and renal abnormalities, termed *reflux nephropathy*. The 3 forms of reflux nephropathy are (1) renal scarring associated with intrarenal reflux of infected urine (commonly seen in older children with primary reflux), (2) congenital nephropathy associated with VUR but in the absence of infection (commonly seen in infants with primary reflux), and (3) nephropathy associated with VUR and impairment of urinary flow (commonly seen in children with secondary reflux).

VUR is most often identified after investigation for other urinary tract problems such as UTI and prenatal hydronephrosis or in evaluation of a family history of VUR. The prevalence of VUR in children without any UTI or urologic anomalies is thought to be from 0.4% to 1.8% of the pediatric population. In children with UTI, the prevalence ranges from 30% to 50%, whereas in children with prenatal hydronephrosis, it is approximately 25%. VUR seems to be heritable; 50% to 67% of the children of parents with VUR and 33% to 50% of the siblings of children with VUR will have the

condition. The incidence of VUR is significantly lower in blacks than it is in whites. Similarly, the incidence of VUR is much lower in boys than it is in girls. However, in infants younger than 1 year, the proportions of boys and girls with VUR are more equivalent. In children with UTI, the ratio of girls to boys with VUR is approximately 4:1, whereas, in infants evaluated for prenatal hydronephrosis, the ratio is the reverse.

### Differential Diagnosis

VUR is diagnosed after evaluation for UTI, prenatal hydronephrosis, or family history of reflux. Less common modes of presentation include hypertension, renal insufficiency or failure, or incidental findings of a small or scarred kidney or hydronephrosis observed on radiologic imaging tests such as US, computed tomography, or magnetic resonance imaging. Young children with UTIs often have generalized signs and symptoms such as fever, vomiting, and failure to thrive. Older children may exhibit more specific signs and symptoms for UTI, such as flank pain, dysuria, and gross hematuria. Differentiating between UTI and other causes of sepsis may be difficult, particularly in young infants. Considerable debate exists as to which children with UTI require a VCUG to rule out VUR. The American Academy of Pediatrics (AAP) 2011 Clinical Practice Guideline "Urinary Tract Infection: Clinical Practice Guideline for the Diagnosis and Management of the Initial UTI in Febrile Infants and Children 2 to 24 Months" recommends that the evaluation for VUR is not necessary in children of this age group who presented with a first-time febrile UTI and had a normal US. However, several studies have indicated that the incidence of VUR in young children, especially circumcised boys, who present with a febrile UTI ranges from 30% to 50%. In contrast, older girls with cystitis, nonfebrile UTI, or asymptomatic bacteriuria are less likely to have VUR and consequently do not always require a VCUG for evaluation. Similarly, whether all children with prenatally diagnosed hydronephrosis require a VCUG to rule out reflux is controversial. The incidence of VUR is low in children with mild hydronephrosis detected on prenatal US, but it increases with the moderate and severe grades. Consequently, a VCUG should be performed in children with a history of moderate or severe hydronephrosis observed on prenatal US. Additional indications for a VCUG include findings on prenatal US of a dilated ureter, abnormal bladder wall thickness, renal echogenicity, renal parenchymal thinning, or decreased amniotic fluid volume.

As noted previously, a strong genetic component exists in the development of VUR. Consequently, screening for reflux in families with VUR may be indicated, with the goal of identifying these children early and decreasing their risk of developing long-term complications from VUR. Screening with a radionuclide cystogram (RNC) should be performed in siblings or offspring who are younger than 5 years. They are the ones with the highest likelihood of having VUR and have the greatest risk of developing renal scarring from pyelonephritis. In older siblings or offspring who have never had any UTIs, a screening US would be sufficient. If a history of UTI or hydronephrosis is present, or if evidence of

parenchymal thinning is present on the screening US, then an RNC is indicated.

### Evaluation

In the evaluation for UTI or prenatal hydronephrosis, a US is usually first obtained. However, US cannot confirm the presence or absence of reflux, because severe reflux may be present in the absence of any significant hydronephrosis (Figure 299-6). In children, the VCUG remains the principal method of detecting and quantifying the degree of VUR. A VCUG is

**Figure 299-6** Normal ultrasound of the right and left kidneys despite the presence of high-grade vesicoureteral reflux as seen on voiding cystourethrogram.

performed by placing a urethral catheter into the bladder, instilling a contrast agent, and obtaining images of the bladder and kidneys during filling and voiding. VUR is diagnosed when contrast instilled into the bladder is detected in the ureter or upper urinary tract (Figure 299-7). The degree of VUR is quantified by the International Reflux Study Group classification system (Table 299-2). In addition to detecting and quantifying the degree of VUR, the VCUG also helps identify other bladder and urethral anomalies, such as PUVs, ureterocele, bladder diverticula, and neurogenic bladder, that may cause secondary reflux.

With the conventional fluoroscopic VCUG, images are captured at fixed time points, and episodic reflux might thus be missed. Consequently, especially in infants, a fill-void cycle should be repeated at least once during the test to improve the sensitivity of the VCUG in detecting VUR. An alternative imaging test is the RNC. A radioisotope (eg, DTPA) is placed in the bladder, and the bladder, kidneys and ureters are continuously monitored (Figure 299-8). Because the imaging is continuous, the sensitivity in detecting reflux with an RNC is increased compared to fluoroscopic VCUG. In addition, the use of the RNC exposes the patient to less radiation compared with conventional VCUG. However, the anatomic details (eg, grade of reflux and associated urethra, bladder abnormalities) cannot be resolved well with RNC. Thus, VCUG should be used as the initial study to identify and characterize the reflux; RNC should then be used for follow-up studies. The VCUG should be performed after the infection has resolved and a repeat urine culture is negative. Instrumentation while the infection is still active may lead to sepsis.

Because renal parenchymal abnormalities are found in association with VUR, proper functional imaging

**Figure 299-7** Vesicoureteral reflux seen on voiding cystourethrogram.

of the kidneys is indicated in patients with reflux. Although US is not invasive or costly, its ability to detect renal abnormalities such as dysplasia and scarring is limited. Renal scanning by DMSA provides an accurate assessment of renal development and permits evaluation for the presence of renal scarring resulting from UTI (Figure 299-9). In the past, intravenous pyelogram has been used to assess renal parenchymal abnormalities. However, it has been replaced by renal scintigraphy as the gold standard because of the increased sensitivity of DMSA scans in detecting renal scarring. Not all children with VUR require imaging with renal scintigraphy. Renal abnormalities such as scarring and dysplasia are more often found in children with at least 1 UTI and in those with higher grades of reflux (grade III and above); therefore, renal scintigraphy is indicated for children with VUR who have at least 1 episode of UTI and those with at least grade III VUR.

Table 299-2 International Reflux Study Classification System for Vesicoureteral Reflux		
GRADE	REFLUX INTO URETER	REFLUX INTO CALICES
I	Distal segment only	None
II	Without tortuosity	Without distention
III	With minimal tortuosity	With mild distention
IV	With moderate tortuosity	With moderate distention
V	With severe tortuosity	With severe distention

**Management**

In most patients, VUR will resolve spontaneously without requiring surgical intervention. Consequently, medical therapy should be considered, with the goal of preventing the long-term complications associated with VUR, such as renal scarring, hypertension, and renal insufficiency or failure by the prevention of UTI. The use of antibiotic prophylaxis for VUR is controversial. It was generally accepted that the use of chronic low-dose antibiotic prophylaxis can prevent UTI and thus prevent the complications associated with VUR. This is based on past studies in which 21% of children with VUR who did not receive prophylactic

**Figure 299-9** <sup>99m</sup>Tc dimercaptosuccinic acid renal scan demonstrating renal scarring in a patient with vesicoureteral reflux.

**Figure 299-8** Vesicoureteral reflux seen on nuclear cystogram.

antibiotics developed new scars in previously normal kidneys, and 66% developed new scars in previously scarred kidneys. In children with similar grades of reflux, but receiving antibiotic prophylaxis, no progression of renal scars occurred unless a breakthrough UTI was present. More importantly, predicting which children would and would not develop renal scarring was impossible. More recently, a meta-analysis in the AAP UTI Clinical Practice Guideline (2011) suggested that there may be no benefit to using antibiotic prophylaxis for VUR. Data from 6 recent studies did not support the use of antimicrobial prophylaxis to prevent febrile recurrent UTI in infants without VUR or with grade I to IV VUR. However, it should be noted that the studies included in the meta-analysis were from vastly different patient populations. In several of the included studies, most of the patients had low-grade VUR, minimal incidence of renal damage, and variable degree of voiding and bowel dysfunction. Four of the studies included patients much older than 2 years of age who more likely had bladder and bowel dysfunction as a risk factor for UTI rather than VUR. Moreover, the circumcision status, another important risk factor for UTI, was not known in 4 of the studies.

The current suggestions for antibiotic prophylaxis are summarized in Table 299-3 and should be maintained until VUR has resolved spontaneously or after surgical correction. In children older than 7 to 8 years who have persistent low-grade VUR but have not had any recent UTIs, observation while they are no longer receiving antibiotic prophylaxis may be tried because the risk of renal scarring in these children is low. Antibiotic prophylaxis can be used as long as no breakthrough UTIs or compliance issues occur. Length of therapy varies depending on parental preference and the likelihood of reflux resolution. When reflux resolution seems unlikely, stopping the antibiotics and correcting the reflux should be considered. Debate is ongoing about whether to use alternating antibiotic prophylaxis versus monotherapy. Most physicians use monotherapy, and very little evidence has been found in the literature that suggests alternating antibiotic prophylaxis is more effective than monotherapy. In teenagers with reflux, a trial of antibiotic is reasonable; however, their chance of resolution is thought to be somewhat lower. The disadvantages of antibiotic prophylaxis include difficulties in adherence to daily schedule, adverse/allergic reaction to the antibiotics,

and the potential for the emergence of microbial resistance.

The spontaneous resolution rate of VUR depends on several factors, including the grade of the reflux, laterality, gender, and mode of presentation. In general, low-grade VUR is more likely to resolve than high-grade reflux (grades I and II, 70% to 80% resolution rate; grade III, 50%; grades IV and V, <30%). Bilateral high-grade VUR tends to resolve less often than unilateral high-grade VUR. VUR in girls tends to resolve at a slower rate than in boys. High-grade VUR detected after evaluation for prenatal hydronephrosis tends to resolve more quickly than that detected after evaluation for UTIs. In patients with sibling reflux, the rate of resolution is similar to the probands, with grade as the primary determining factor.

Voiding dysfunction can greatly affect the resolution rate of VUR. Voiding abnormalities, such as detrusor instability or detrusor-sphincter dyssynergy, can impede the resolution of reflux, and, in some patients, it can worsen its severity with time. Consequently, in the medical management of reflux, symptoms of dysfunctional voiding, such as urinary urgency and incontinence, must be ascertained, and treatment of dysfunctional voiding with timed voiding, anticholinergic therapy, or both, must be instituted. Similarly, constipation can increase the risk of UTI and delay the resolution of VUR. Aggressive treatment of constipation will help decrease the risk of UTI and improve voiding function.

In some patients, surgical correction for VUR may be required. Recurrent UTI while receiving prophylactic antibiotic therapy is an indication for surgical correction, because protection from renal scarring cannot be adequately achieved with medical management. Additional indications for surgery include lack of compliance with a medical regimen, low probability of spontaneous resolution of reflux (eg, in older children with higher-grade reflux), new renal scar formation while receiving prophylaxis, and anatomic abnormalities such as a paraureteral diverticulum. The overall rate of surgical correction in a general population of children with all grades of VUR ranges from 13% to 20%. The types of surgical correction include transurethral (endoscopic), laparoscopic, and open techniques. The open antireflux procedures have a high success rate (98%), but often require a few days of hospitalization and subsequent recovery time. In contrast, the endoscopic techniques have much lower associated morbidity and shorter recovery time; however, their success rates are not as good as that of open surgery.

In the management of reflux, the goal is not merely to prevent UTIs and to determine whether VUR has resolved. The primary care physician should monitor children for long-term complications such as reflux nephropathy. Approximately 10% of children and 50% of adults with renal scarring will develop hypertension. In addition, estimates suggest that approximately 10% of children with reflux nephropathy will develop end-stage renal disease, and 90% will have diminished glomerular filtration rate. Consequently, blood pressure and urinary protein levels should be measured periodically if renal scarring is present. Women with a

**Table 299-3** Antibiotic Prophylaxis Suggestions

AGE	MEDICATION	DOSAGE
<3 months	Amoxicillin	25 mg/kg once a day
	Cephalexin	25 mg/kg once a day
>3 months	Trimethoprim	2 mg/kg (up to 100 mg) once a day
	Trimethoprim + sulfa	2 mg/kg of the sulfa once a day
	Nitrofurantoin	1–2 mg/kg (up to 100 mg) once a day

history of VUR and in particular with reflux nephropathy should be monitored closely during pregnancy because of the increased rates of pyelonephritis, toxemia, preterm delivery, fetal growth retardation, fetal loss, and decreased maternal renal function.

## Chapter 300 OCULAR TRAUMA

Rajesh C. Rao, MD; Lisa Bohra, MD; John D. Roarty, MD, MPH

### INTRODUCTION

Accidental ocular trauma represents a major public health issue. Although only 5% of all eye injuries are serious enough to result in permanent visual loss, trauma accounts for 40% of all cases of monocular blindness in the general population. In addition to the obvious visual consequences, severe trauma in children can also present significant developmental and emotional challenges, especially if a cosmetic defect is present. Amblyopia can develop after injury in

children younger than 8 years, placing an additional physical and psychological burden.

Demographic data from several studies demonstrate that boys are more susceptible to ocular injury than girls, with a ratio of approximately 3:1. Common sources of injury include interactions with other children, sports, motor vehicle crashes, falls, and projectiles. Among sports-related injuries, baseball was most common, followed by basketball, tennis, and hockey. In children who had visual outcome of 20/200 or worse, BB guns, knives, and rocks were commonly implicated. Mandatory eye protection in organized sports such as hockey has significantly reduced eye injuries, but commonsense precautions are not always exercised on the playground or at home. Most severe injuries occur in children with no eye protection, whereas only 5% occur in those who are wearing safety glasses or regular glasses. Pediatricians and eye care providers should actively educate parents and children regarding the importance of eye protection to prevent ocular injuries.

### ANATOMIC CONSIDERATIONS

The orbit is a pear-shaped cavity in the skull that protects the globe from lateral injury. The orbital rim tends to absorb the impact of most blunt injury with large objects such as a ball or fist. The medial wall and orbital floor are thinner and susceptible to fracture, whereas the lateral wall is the thickest and strongest. The orbital roof is also the floor of the anterior cranial fossa; therefore an orbital roof fracture requires neurosurgical evaluation. Any child with an orbital fracture must undergo a careful eye examination to rule out globe injury.

The eyelids protect the globe from debris and direct trauma involving smaller objects. The eyelids are also vital in maintaining a normal smooth tear film over the cornea. Injury to the eyelid, particularly if it involves the lid margin, can result in exposure of the cornea and lead to scarring or infection. Deeper injury to the lids can be associated with globe injury or injury to the levator muscle if the orbital septum has been violated. The lacrimal drainage system starts in the medial aspect of the upper and lower lid at the punctal opening and connects to the lacrimal sac and bony nasolacrimal duct through canaliculi. An eyelid injury medial to the punctal opening frequently results in a canicular laceration, which requires surgical repair.

The globe rests in the orbit, cushioned by orbital fat and suspended by its attachment to extraocular muscles and surrounding elastic tissues. The exposed structures in the interpalpebral fissures are the cornea and conjunctiva, which are frequently involved in eye injuries. The cornea is 0.5 mm thick centrally and 1 mm thick at the periphery. A corneal injury that is limited to the epithelium often resolves without sequelae, whereas an injury that penetrates the epithelial basement membrane into the stroma can result in permanent scarring and vision loss. The bulbar conjunctiva extends from the corneal limbus and covers the sclera. It then forms the cul-de-sac or fornix and reflects over the inner surface of the eyelids as the palpebral conjunctiva. Hemorrhages in the subconjunctival space are usually benign but can hide deeper

injuries to the sclera or extraocular muscles. The sclera covers the posterior four-fifths of the globe and is largely avascular. It is 0.5 mm thick at the equator and 1 mm in thickness posteriorly. The sclera is thinnest (0.3 mm) just behind the insertion of the rectus muscles, making this area a common site for globe rupture after blunt trauma. The iris is the most anterior portion of the uveal tract, the vascular coat of the eye. Trauma can result in bleeding or tears in the iris, especially at its root where it is thinnest. The lens is located just behind the iris and is entirely covered by a capsule. Disruption of the capsule as a result of sharp or blunt trauma can compromise the clarity of the lens, resulting in a traumatic cataract.

The posterior segment of the eye comprises the posterior sclera, choroid, retina, and vitreous. The macula represents the critical central portion of the retina, which is responsible for fine visual acuity. Severe trauma can result in vitreous hemorrhage and retinal edema, retinal tears, and retinal detachment. Injury affecting the macula can result in severe central vision loss, whereas damage to the peripheral retina can be asymptomatic. In general, trauma affecting the posterior segment structures usually carries a worse prognosis for recovery than injury limited to the anterior segment.

## EVALUATION

### History

An accurate and detailed history is helpful in evaluating a patient with ocular trauma because it can suggest the mechanism and nature of injuries. This history can be difficult to obtain in circumstances in which an adult or other reliable observer did not witness the injury, and details obtained from young children may not always be reliable. In such instances, the pediatricians must verify that the physical findings are consistent with the history obtained. Certain historical details are particularly helpful:

1. Does a potential exist of chemical injury? If so, then treatment must be delivered immediately before obtaining a full history and performing an examination to minimize damage from an acid or alkali burn.
2. Has a severe head injury or other nonocular injury occurred that may require attention? Significant head trauma can be associated with globe rupture, traumatic optic neuropathy, cranial nerve palsies, orbital fractures, and cortical visual damage.
3. Is the injury blunt or sharp in nature? A sharp injury is more likely to be penetrating, resulting in a full-thickness laceration through the cornea or sclera. A severe blunt impact can also lead to globe rupture through an inside-out mechanism as a result of globe compression and increased intraocular pressure.
4. Does the possibility exist of a foreign body? A foreign body can be superficial (in the eyelid, cornea, or conjunctiva), intraocular, or intraorbital. An injury associated with flying debris, metallic fragments, projectiles, or any broken object is high risk for a retained foreign body.

After details surrounding the mechanism of injury have been obtained, additional history taking should

focus on prior ocular history (eg, the presence of amblyopia), medical history, medications and allergies, and the date of the last tetanus immunization.

### Physical Examination

A thorough and complete examination ensures proper diagnosis and treatment, particularly when historical details are lacking. If the history is clear and reliable, such as being poked in the eye with a finger, then a more directed examination is possible. An examination can be quite challenging in a child who is in discomfort or who is otherwise uncooperative. If a full-thickness injury through the eyeball is apparent, then further examination is best left to an ophthalmologist. If the index of suspicion for a serious injury or foreign body is high in an uncooperative patient, then examination under sedation or anesthesia is occasionally necessary.

### Vision Testing

The examination should begin with an age-appropriate assessment of vision. Verbal children should have acuity measured with letter charts or, if they cannot name the letters, with letter matching (such as the HOTV chart) or other nonletter testing, such as Allen pictures or tumbling Es. Acuity testing should be performed with proper optical correction, if applicable, and care should be taken to ensure that the normal eye is fully occluded when testing the injured eye. If the child is unable to see the largest target on the chart (usually 20/200 or 20/400), then alternative methods such as their ability to count fingers (recorded as “count fingers at x feet”), perceive hand motion (recorded as “hand motion at x feet”), or perceive light (recorded as “light perception” or “no light perception”) is helpful. Preverbal children are assessed by their ability to *fix and follow* a small object or toy. Once again, each eye should be tested separately. An inability to follow smoothly with 1 eye compared with the other or attempts to look around the occlusion of the normal eye suggest decreased vision in the injured eye.

### External Examination—Ocular Motility

External inspection and observation are helpful to characterize the severity of the injury. Important signs include swelling or bruising of the lids, lacerations of the lids or face, proptosis or enophthalmos, foreign bodies and possible entrance sites, and conjunctival hemorrhage. If a foreign body is likely, then eversion of the upper lid is required to inspect the palpebral conjunctiva properly. An obvious globe laceration with prolapse of intraocular contents might also be visible by inspection alone. If the globe appears intact, then palpation of the orbital rim can be performed to check for fractures of the orbital or facial bones. Ocular motility should be evaluated to ensure full range of motion in all gaze positions. Limited movement can result from orbital hemorrhage or swelling, orbital fractures, cranial nerve palsies, or direct muscle trauma. Diplopia generally results from limited motility, although young children may not verbalize this symptom.

### Pupils

The presence of round and equally reactive pupils greatly reduces (but does not eliminate) the likelihood

of a severe, vision-threatening injury. An irregularity in the size or shape of the pupil can result from blunt trauma with damage to the pupillary sphincter or from a full-thickness laceration of the cornea or sclera. Ideally, the reaction of each pupil to light (direct and consensual) is checked with the child fixating at a distant target. The swinging flashlight test is then performed to check for the presence of an afferent pupillary defect, or Marcus Gunn pupil. This test is performed by alternately shining the light source into each eye. Both pupils should normally stay constricted as a result of the direct and consensual response to light. Paradoxical dilation of the illuminated pupil indicates the presence of an afferent pupillary defect, which results from optic nerve or extensive retinal injury.

### Anterior Segment

An initial assessment of the anterior chamber can be performed simply with a penlight examination or with a direct ophthalmoscope. Conjunctival hemorrhages, corneal or conjunctival lacerations, foreign bodies, anterior chamber depth, and iris and pupillary irregularities can be diagnosed without the aid of the slit lamp. If a slit lamp is available, then a more detailed and accurate examination is possible in a cooperative child. The pediatrician can use the slit lamp to evaluate for smaller conjunctival or corneal lacerations, foreign bodies that might not be visible with a penlight, the presence of red or white blood cells in the anterior chamber, and cataract formation or dislocation of the lens. After penlight or slit-lamp or both types of examination have been completed, fluorescein solution or strips and a cobalt blue filter or lamp should be used to check for abrasions, lacerations, or foreign bodies that might otherwise go undetected.

### Fundus

Detailed fundus examination can be difficult in a child without pupillary dilation. However, the red reflex should be observed, looking for asymmetry. An absence or asymmetry of the red reflex can indicate the presence of vitreous hemorrhage, cataract formation, or hyphema. In addition, other findings such as corneal abrasion or corneal foreign body can also be appreciated as an irregularity or opacity in the red reflex. Although visualization of the optic nerve and macula is possible with the direct ophthalmoscope, the view is generally limited. Any child who is thought to have posterior segment injury or unexplained vision loss should have a dilated fundus examination by an ophthalmologist with the aid of the indirect ophthalmoscope.

## SPECIFIC OCULAR INJURIES

### Eyelid and Lacrimal Injury

Superficial lacerations to the eyelid can be closed with 6-0 nylon sutures, which are removed in 5 to 7 days, or 6-0 plain sutures if the child might be uncooperative for suture removal. A thorough examination of the anterior segment is required to exclude globe injury. Three special categories of eyelid injuries require special attention: lacerations involving the lid margin, lacerations medial to the lacrimal puncta, and deep lacerations of the upper lid, which expose orbital

**Figure 300-1** Full-thickness injury involving the lid margin and lower canaliculus. The laceration is medial to the lacrimal punctum.

fat. Lacerations involving the lid margin should be repaired by an experienced surgeon to ensure that the smooth contour of the lid margin is maintained. Poor closure or reapproximation can result in a notch along the lid margin, leading to both cosmetic and functional consequences. Laceration or injury medial to the punctum carries a high risk for disrupting the lacrimal drainage system, given that the canaliculus is quite superficial just under the surface of the lid margin (Figure 300-1). Failure to recognize and treat a canalicular laceration can result in chronic tearing, particularly if the lower canaliculus is involved. A canalicular injury requires prompt referral and surgical repair with tube placement in the lacrimal drainage system, followed by removal of the tube several months later. Dog bite injuries have an uncanny predilection for involving the lacrimal system. Upper lid lacerations deep enough to expose orbital fat carry the risk for damage to the levator muscle. Surgical exploration is required to repair any involvement of the levator muscle and to close the laceration itself. Failure to recognize levator involvement can result in posttraumatic ptosis, which might require additional surgery.

### Anterior Segment Trauma

#### Chemical Injury

Chemical injuries are acute emergencies and require immediate management to help prevent serious complications. Typically, the caregiver or emergency medical services will have attempted to irrigate the eyes, but it is often difficult to do so sufficiently. When a child reaches the pediatrician's office or emergency care setting after a chemical injury, the history should be limited to the estimated time of injury and nature of the offending agent (eg, household cleaning product).

A helpful first step is to use pH indicator paper to determine the nature and extent of acid or alkali injury. A small strip can be quickly placed in the conjunctival sac; normal pH of the eye is between 6.8 and 7.4. Topical anesthetic should be instilled, and the eye irrigated with up to 2 liters of a pH-neutral solution,

such as buffered saline. A lid speculum may be used to keep the lids open if necessary. Alternatively, an irrigating contact lens can be used. Care must be taken to ensure the flow of saline is adequate; a steady drip is usually not sufficient. When irrigation is completed, pH indicator paper can again be used to determine that the pH of the eye has returned to normal. The conjunctival fornices should be examined to check for any residual chemical agent. If present, then a cotton-tipped applicator may be used to gently remove this precipitate, and the area should be reirrigated.

After irrigation, a more detailed examination should be performed. First, the examiner should note the degree of conjunctival injection. A lack of hyperemia, particularly in the perilimbal area, may be an ominous sign of ischemia. Permanent damage to stem cells located in this area can significantly impair the patient's ability to regenerate corneal epithelial cells. Second, the cornea should be examined for clarity. A hazy or edematous cornea is a sign of serious injury. Finally, the examiner should instill fluorescein to check for corneal abrasions.

Treatment should be tailored to the injury but will often include an antibiotic drop or ointment and artificial lubricants. Corneal abrasions associated with chemical injuries should not be patched so that tears and natural blinking may eliminate any residual chemical. Referral to an ophthalmologist within 24 hours is indicated, particularly with moderate to severe injuries, which can result in permanent vision loss from corneal scarring, corneal vascularization, and other sequelae.

### Thermal Injury

Ocular involvement from thermal injury can be isolated but is often seen in the setting of severe facial burns. Although globe injury is typically mild because of the protective blink reflex, it can be severe if the blink reflex is impaired or if loss of consciousness occurs. As with chemical injuries, immediate irrigation is important, given that it serves to cool the ocular surface. Corneal and conjunctival abrasions are treated with artificial lubricants and topical antibiotics. Severe lid involvement can lead to contracture and cicatricial changes resulting in corneal exposure and ulceration. Initial treatment of lid injury consists of topical antibiotic ointment, and severe injury may require subsequent skin grafting to prevent lid malposition and exposure.

### Subconjunctival Hemorrhages

Significant discoloration is associated with subconjunctival hemorrhages; this condition may be quite alarming to patients and their families (Figure 300-2). When isolated, however, they are harmless and require no treatment. Patients need only be aware that various color changes may occur while the blood is being resorbed and that several days to weeks may elapse before the hemorrhage has completely disappeared.

Surrounding blood can mask tissue laceration. A small, superficial laceration of the conjunctiva often does not require repair, but a thorough ophthalmic examination may be necessary to ensure that no

**Figure 300-2** Subconjunctival hemorrhage after blunt injury.

deeper laceration of the sclera or other trauma to the eye has occurred.

Nontraumatic causes of subconjunctival hemorrhage also exist. Newborns often have small, bilateral hemorrhages, presumably from the pressure of uterine contractions. Severe coughing such as that caused by pertussis or forceful vomiting can cause small hemorrhages. Some forms of viral conjunctivitis can be hemorrhagic and are usually associated with chemosis (edema of the conjunctiva) and symptoms of irritation and mild discharge. Rarely, certain blood dyscrasias such as leukemia can also be associated with subconjunctival hemorrhage, usually bilateral.

### Corneal Abrasion

Corneal abrasions are areas of disruption of the corneal epithelium. The epithelium is laced with numerous fine sensory nerve endings of the first branch of the trigeminal nerve, and abrasions result in extreme pain and sensitivity. Only in rare situations of neurotrophic disease are corneal abrasions relatively asymptomatic. Typically, photophobia and blepharospasm accompany the pain. Associated signs usually include conjunctival injection and mild lid swelling.

Diagnosis of a corneal abrasion may be facilitated by the instillation of a topical anesthetic followed by fluorescein (Figure 300-3). Use of a cobalt blue filter will then easily highlight areas of epithelial loss. Abrasions may be linear or patchy and can be of any size. Care must be taken to open the lids well enough to gain view of the entire cornea. Fine, linear abrasions in the superior cornea, for example, may be easily missed and are often a sign of an associated conjunctival foreign body lodged in the superior tarsal conjunctiva.

Most abrasions heal quickly, particularly in children. Treatment is aimed at keeping the patient comfortable and preventing infection. Typically, an antibiotic ointment or drop is used 2 to 4 times a day until the abrasion has healed. Nonsteroidal anti-inflammatory drops may be used as an adjunct to reduce pain, particularly in older children. The use of a pressure patch is somewhat controversial. When a patch is used, an antibiotic

**Figure 300-3** Central corneal abrasion is highlighted with fluorescein dye.

ointment is instilled with soft oval gauze taped over the eye to keep it shut. The patch and antibiotic are then replaced after 24 hours, or the decision is made to discontinue its use. Prolonged patching is discouraged for young children because of the possibility of developing amblyopia or strabismus. The placement of a patch may provide additional patient comfort and may be particularly useful if a child tends to rub the eye excessively. However, no evidence has been found to suggest the abrasion will heal more quickly. Some ophthalmologists think that allowing natural tears, which contain immunoglobulin A, lysozyme, and other anti-infective properties, to stream over the cornea with normal blinking may result in improved healing and decreased risk for infection. Whichever method is used, the patient should be monitored closely, especially within 1 to 2 days, for delayed healing. Delayed healing may suggest the presence of a foreign body, an ulcer, or even a different pathologic process (eg, herpes keratitis).

### Conjunctival and Corneal Foreign Bodies

The sources of most surface, or nonpenetrating, foreign bodies in children are small objects that can be thrown or carried by the wind, such as dirt, sand, gravel, grass, or leaves. In many instances, the foreign body will be readily eliminated from the eye with rubbing and secondary tearing. In some cases, however, medical attention is necessary to help dislodge the foreign material.

Conjunctival foreign bodies typically produce irritation, discomfort, and a mild to moderate amount of conjunctival injection. The lids should be forcefully opened, if necessary, and the bulbar conjunctiva should be directly examined. If this area appears normal, attention is then turned to the tarsal conjunctival surfaces. Eversion of the lower lid can be accomplished readily with gentle inferior traction. Upper lid eversion can be much more difficult, especially if the child is very young or uncooperative. The lashes are grasped and the lid stretched minimally; next, the shaft of a cotton-tipped applicator is placed horizontally along the superior margin of the tarsal plate. The lid is then reflected over the applicator for inspection. After a conjunctival foreign body has been identified, a drop of topical anesthetic should be administered

**Figure 300-4** Fine, linear abrasions of the superior cornea are luminated with fluorescein dye and the use of a cobalt blue filter.

**Figure 300-5** Eversion of the upper lid reveals a small particle resting in the superior tarsal conjunctiva.

and a cotton tip used to remove it gently. If a conjunctival foreign body is not easily identified, then a cotton tip may still be used to sweep the upper and lower conjunctival fornices to ensure that a very small foreign particle has not been missed. Finally, fluorescein should be administered to check for associated corneal abrasions. Multiple, fine vertical abrasions of the superior aspect of the cornea are highly suggestive of a foreign body of the upper tarsal conjunctiva (Figure 300-4 and Figure 300-5).

Corneal foreign bodies usually represent particles that are resting on the surface of the epithelium or have penetrated the epithelium and are embedded in the anterior stroma. The latter types are more common because the normal blink and secondary movement of the tears will usually either expel a nonembedded particle or move it to a conjunctival surface. Again, the lids should be opened to gain full view of the cornea and a light source used to help identify a possible foreign body. A topical anesthetic and cotton-tipped applicator can be used to dislodge

the particle gently, with care taken not to debride a greater area of epithelium in the process. In many instances, however, this method is not successful in removing an embedded object, and referral to an ophthalmologist is necessary. If the child is able to sit at a slit lamp, then the ophthalmologist may be able to use a fine needle, forceps, or burr to remove the foreign body. Younger or uncooperative children will usually require sedation or general anesthesia.

An antibiotic drop or ointment is typically prescribed for a few days after removing a surface foreign body, particularly if the source was organic or if any disturbance occurred in the corneal epithelium. Follow-up care is not necessarily indicated for a simple conjunctival foreign body but is required in cases of corneal involvement.

### Hyphema

The presence of blood in the anterior chamber is termed a *hyphema* (Figure 300-6). In the setting of blunt trauma, blood in this area results when enough force is transmitted to the globe to cause a rupture of the blood vessels located within the iris root and ciliary body. Hyphemas can be of varying severity, from what is labeled as a *microhyphema* (floating red blood cells in the aqueous fluid without layering) to an *8-ball hyphema* (blood filling the entire anterior chamber). Most cases fall in between and are described based on the percentage of the anterior chamber occupied by the layered blood. Hyphemas are readily identified with a light source and good exposure of the anterior segment. After diagnosis, initial management involves placing a protective shield over the eye to avoid the possibility of further injury. Patients should also be instructed to limit their activities until seen by a specialist. Because of their potential vision-threatening complications, all hyphemas, regardless of size, should be referred to an ophthalmologist.

Most ophthalmologists treat hyphemas with a topical steroid drop to reduce the associated inflammation, and a topical cycloplegic agent. A shield is usually continued and bed rest often advised. If the

**Figure 300-6** Small hyphema is associated with an iris root tear at the 2-o'clock position.

hyphema is worrisome and the child is too young to cooperate with restricted activity, then hospitalization may be indicated. This circumstance is of particular importance in the first 2 to 5 days after injury, at which time the clotted blood may begin to resorb and cause a rebleed of injured vessels. In many instances, this rebleed can be more visually devastating than the original injury. Other direct complications of hyphemas include corneal blood staining, glaucoma, and amblyopia. Glaucoma is perhaps the most common of the aforementioned complications. It is often controlled with topical medications but, in certain situations, requires timely surgical evacuation of the hyphema to prevent irreversible optic nerve damage. Patients with sickle cell anemia or trait are at greater risk for having visual compromise from optic neuropathy or central artery occlusion at lower pressures than is the general population and therefore require the surgeon to have a lower threshold for intervention.

### Traumatic Iritis

Iritis, or anterior uveitis, refers to inflammation of the iris and ciliary body. This inflammation can occur in a nontraumatic setting, such as in association with autoimmune disorders; it may also occur in the setting of trauma and will cause the patient to experience blurry vision, pain, and significant photophobia. The eye is usually quite injected, and the pupil may not constrict briskly. If iritis is suspected, then referral to an ophthalmologist is indicated. Floating white blood cells in the anterior chamber are visualized under the high magnification of a slit lamp, confirming the diagnosis. Similar to a hyphema, potential complications include iris synechiae, glaucoma, and cataract formation. Treatment includes a topical steroid and cycloplegic agent if the inflammation is severe.

### Traumatic Mydriasis

A mid-dilated pupil noted on examination of a patient after a blunt, traumatic event can be a result of small ruptures or tears of the iris sphincter muscle. The pupil is therefore unable to constrict normally. The injury may involve only part of the sphincter muscle, giving a slightly irregular appearance to the pupil. Care must be taken to rule out the possibility of a ruptured globe, which can also cause an irregularly shaped pupil.

Often, the ophthalmologist is able to identify free pigment cells released into the anterior chamber. However, unless true associated inflammation (iritis) exists, treatment is usually not indicated.

### Open Globe Injury

An open globe results from a full-thickness injury to the eye wall, involving the cornea or sclera. Most open globe injuries in children are caused by a penetrating injury, but they can also result from severe blunt trauma. Penetrating injuries consist of laceration of the globe with sharp objects such as knives, sticks, pencils, and glass. Severe blunt trauma can cause compression of the globe, leading to elevated intraocular pressure and rupture of the eye wall (ruptured globe). Common sources of blunt trauma include

motor vehicle crashes, fist injuries, and sports injuries (eg, baseball, racquetball). The corneoscleral limbus and the sclera just behind the rectus muscle insertions are the thinnest and most susceptible areas for rupture.

The diagnosis of an open globe is often readily apparent when an anterior laceration with exposed intraocular contents is visible. This can lead to a shallow anterior chamber, irregular pupil, and exposed iris or uveal tissue (Figure 300-7). Other anterior segment findings may include subconjunctival hemorrhage, lowered intraocular pressure, and cataract formation. With blunt trauma or with posterior lacerations, the diagnosis may be more difficult, particularly if extensive subconjunctival hemorrhage obscures visualization of the sclera. External signs may consist of an irregular pupil, a deep anterior chamber, subconjunctival hemorrhage, or conjunctival chemosis. When the diagnosis is not evident from initial inspection with a penlight, further assessment with slit-lamp examination, intraocular pressure measurement, and dilated fundus examination may be required. A low intraocular pressure, vitreous hemorrhage, or retinal detachment can occur secondary to a rupture. Other associated clinical findings in an open globe injury may include vision loss, an afferent pupillary defect, and optic disc edema.

The likelihood of an intraocular foreign body should be considered based on the mechanism of injury. A history involving a BB or pellet gun, broken glass, or metal fragments certainly elevates the risk for an intraocular foreign body, but the possibility must be considered with any penetrating injury. The penetration site may not always be evident, and the presence of hyphema or vitreous hemorrhage may preclude visualization of an intraocular foreign body. A B-scan ultrasound or computed tomography (CT) scan should be obtained in such cases, but magnetic resonance imaging is contraindicated if a metallic foreign body is suspected. Copper and iron are toxic to the retina and require urgent removal, whereas graphite, lead, aluminum, and plastic are better tolerated by the eye.

When an open globe injury (with or without intraocular foreign body) is diagnosed or suspected, a

protective shield should be placed over the eye, and further examination should be deferred. The patient should be placed on bed rest with instructions to remain NPO. Urgent ophthalmology consultation is required for surgical repair, with the primary goal to restore the integrity of the eye wall. Surgical exploration of the globe is required in some cases to determine when an open globe injury is present. Additional surgery may be required to manage complications such as traumatic cataract, intraocular hemorrhage, and retinal detachment. The prognosis depends on the severity of the injury, with visual outcomes ranging from 20/20 to NLP (no light perception), whereas enucleation may be required in the most severe cases. In general, injuries that lead to a retinal detachment carry a worse prognosis than those that are limited to the anterior segment. Another serious complication is the development of endophthalmitis, which has been reported to occur in up to 15% of cases after open globe injury.

### Orbital Trauma

Blunt or penetrating trauma may cause severe orbital injury in the absence of an open globe, although diagnosis and management of an open globe take precedence. The most common orbital injuries consist of orbital fractures, retrobulbar hemorrhage, and traumatic optic neuropathy. Evaluation includes assessment of visual acuity, motility, pupils, anterior segment, and intraocular pressure. Obvious proptosis or enophthalmos should also be noted. A marked decrease in vision, presence of an afferent pupillary defect, or elevation of intraocular pressure warrants an urgent ophthalmology consultation.

Orbital fractures typically result from blunt trauma, often with an object such as a fist or a ball. The fracture can occur from increased orbital pressure or from transmission of force from the orbital rim to the orbital walls. The orbital floor is most commonly affected, followed by the medial wall. Involvement of the orbital roof, or the presence of other facial fractures, may require consultation with specialists from neurosurgery or otolaryngology. Common clinical findings with floor fractures include enophthalmos, facial hypesthesia from infraorbital nerve injury, and strabismus from inferior rectus entrapment or cranial nerve injury. A CT scan of the orbits with axial and coronal sections is required to delineate the extent of the fracture. In the absence of globe injury, surgical intervention can be deferred for up to 2 weeks to allow the swelling to subside, although earlier intervention has been reported to improve outcomes. Indications for surgery include the presence of a large defect in the orbital floor, enophthalmos, and tissue entrapment.

Retrobulbar hemorrhage can occur from blunt or penetrating trauma as a result of shearing or laceration of orbital blood vessels. Iatrogenic hemorrhage can occur with peribulbar and retrobulbar injections, typically used to achieve local anesthesia for ocular surgery in adults. Clinical findings consist of rapid-onset proptosis, increased intraocular pressure, limited eye movement, and decreased vision. In the presence of a marked elevation of intraocular pressure or compromised optic nerve function, a lateral canthotomy

**Figure 300-7** Corneal laceration at the 7-o'clock position with exposed intraocular contents, peaked pupil, and shallow anterior chamber.

and cantholysis are required to urgently relieve the retrobulbar pressure on the globe and optic nerve.

Neurologic findings with facial trauma may include cranial nerve palsies and optic neuropathy, typically from blunt trauma involving motor vehicle crashes or sports injuries. A patient with traumatic optic neuropathy may demonstrate decreased vision, an afferent pupillary defect, and decreased color vision. The optic nerve may appear normal or edematous. A CT scan of the orbits may demonstrate a fracture of the optic canal with impingement of the optic nerve or hemorrhage of the optic nerve sheath. Surgical decompression of the optic nerve can be considered in such cases. Standard medical treatment of traumatic optic neuropathy is high-dose intravenous steroids for 1 to 3 days after the injury. However, the efficacy of both surgical and medical interventions remain uncertain.

### Abusive Trauma

Up to 40% of pediatric abuse trauma cases are associated with ocular injuries. Certainly, retinal hemorrhages associated with a shaking injury are of primary concern, but many other signs of eye trauma exist. Direct blunt force can result in multiple injuries, such as lid ecchymosis, orbital fracture, and intraocular hemorrhage. Neurologic injury can result in cranial nerve palsies, which in turn may cause lid and ocular motility abnormalities. Cortical visual impairment may also occur in the setting of severe neurologic damage.

Pediatric sexual abuse can rarely manifest as conjunctivitis caused by *Chlamydia trachomatis* or *Neisseria gonorrhea*. Although these are potential etiologies of neonatal conjunctivitis transmitted by passage through the birth canal, any child outside of the newborn period with a culture positive for these organisms should be suspected as a victim of sexual abuse. *Phthirus pubis* can uncommonly be found on the eyelashes and eyebrows of children and is termed *phthiriasis palpebrarum*. Sexual abuse must also be suspected in these cases,

although some children have been known to become infected from sharing a communal bed with heavily infested adults.

Retinal hemorrhages are a key manifestation of abusive head trauma in children younger than 5 years and are present in up to 85% of cases of abusive head trauma (also known as *shaken baby syndrome*) (Figure 300-8). There is a positive association between the level of neurologic injury (including subdural and subarachnoid hemorrhage) and the severity of retinal hemorrhages.

The hemorrhages are thought to occur secondary to violent, repetitive, acceleration-deceleration maneuvers, causing vitreoretinal traction and subsequent bleeding. This blood can accumulate in 1 or more of several locations, and the presence of multilayered hemorrhages is a key characteristic of nonaccidental trauma. Blood between the retina and underlying choroid is termed *subretinal*; blood in the retina is termed *intraretinal*; blood in front of the inner limiting membrane but behind the vitreous gel is termed *preretinal*. Intrasclear hemorrhage at the optic nerve-globe junction, as well as macular schisis (splitting of the retinal layers) and perimacular folds, are felt to occur predominantly, but not exclusively, in cases of abusive head trauma.

The medicolegal implications of discovering retinal hemorrhages are of course profound, and the determination of whether abuse has occurred should be made after the careful consideration of several factors, including the history, presence of intracranial hemorrhage, fractures, and other signs of abuse. There are multiple other causes of retinal hemorrhages, including (but not limited to) anemia, coagulopathy, leukemia, cytomegalovirus infection, hypertension, and glutaric aciduria. However, many of these can be ruled in or out by the presence of other ocular findings, such as infiltrates in the case of leukemia or exudates in the case of hypertension. Birth trauma can also cause

**Figure 300-8** A, Severe retinal hemorrhages as the result of abusive head trauma. B, Moderate retinal hemorrhages as a result of abusive head trauma. Preretinal hemorrhages, which obscure the retinal vessels, and intraretinal hemorrhages, which are beneath the retinal vessels, are both visualized.

retinal hemorrhages, but these are typically small, few in number, and restricted to the area of the posterior pole. Furthermore, they usually resolve anywhere from 3 days to 6 weeks after birth. Few other etiologies other than abusive head trauma exist for severe, multilayered retinal hemorrhages.

When abuse is suspected, the pediatrician should consult an ophthalmologist within 72 hours of presentation and ideally within 24 hours. If pharmacologic dilation of both pupils is not possible for the sake of neurologic monitoring, then sequential examinations should be performed on each eye. If appropriate equipment is available, retinal photographs should be obtained. The examiner should make sure to document well the number, location, and type of retinal hemorrhages and other pathology seen. Lastly, follow-up care with the ophthalmologist is indicated to help assess long-term vision potential.

### WHEN TO REFER

- Lacerations involving the lid margin, those medial to the lacrimal puncta, and deep lacerations of the upper lid
- Canalicular injury
- Levator muscle injury
- Corneal abrasion
- Removal of corneal foreign bodies
- Hyphema treatment
- Traumatic iritis
- Traumatic mydriasis
- Ruptured globe
- Abusive trauma

### WHEN TO ADMIT

- To treat hyphemas in certain patients
- Ruptured globe
- Abusive trauma

## Chapter 301

## OLIGURIA AND ANURIA

Amrish Jain, MD; Tej K. Mattoo, DCH, MD

A decrease in urine output is the most visible sign of acute kidney injury (AKI) in all age groups, particularly younger children. *Oliguria* occurs when the urine output in an infant is less than 0.5 mL/kg per hour for 24 hours or is less than 500 mL/1.73 m<sup>2</sup> per day in older children. *Anuria* is defined as absence of any urine output. An important point to remember is that healthy newborns may have no urine output for 24 hours after birth.

Oliguria is much more common than anuria, and, if not treated appropriately, the patients may become anuric, which may result in serious renal damage that requires specialized care. Oliguria or anuria may be the outcome of a renal response to intravascular circulatory volume depletion or a sudden drop in blood pressure (*prerenal AKI*). Oliguria or anuria may also occur as a result of intrinsic renal damage (*renal AKI*). Rarely, obstruction to the flow of urine (*postrenal AKI*) may result in oliguria or anuria.

### INCIDENCE

The incidence of oliguria or anuria in previously healthy children is not known, particularly oliguria because many such patients have subclinical symptoms or respond promptly to appropriate management, and thus they are not reported in the literature.

In hospitalized patients, oliguric AKI occurs in approximately 10% of newborns in the intensive care unit, 2% to 3% of older children requiring intensive care, and 8% of patients undergoing cardiac surgery. In newborns, the relative incidence of prerenal, renal, and postrenal AKI is 85%, 11%, and 3%, respectively. In older children, the corresponding data extrapolated from studies are 66%, 33%, and less than 1%, respectively.

### ETIOLOGY

The common causes for oliguria, anuria, or AKI in children are best defined in relation to the age of the patient.

Prerenal AKI caused by dehydration is the most common cause of oliguria and anuria in younger children, accounting for 70% of community-acquired cases of AKI and up to 60% of hospital-acquired cases.

Recent literature reveals that the etiology of AKI is changing from predominantly primary renal disease to multifactorial causes. In hospitalized children, nephrotoxic medication is emerging as one of the most common causes of renal AKI. Renal AKI caused by intrinsic renal damage may be further categorized into 4 types: (1) *Acute tubular necrosis* (ATN) occurs as a result of prolonged ischemia or drug- or toxin-mediated renal tubular injury. Oliguria reverses in most cases after repair and regeneration of tubular epithelial cells occurs. (2) *Glomerular lesions* may occur with acute glomerular diseases, including postinfectious glomerulonephritis. (3) *Vascular lesions* may be seen in hemolytic uremic syndrome or vasculitis. (4) *Interstitial lesions* occur in acute interstitial nephritis, mostly as a result of drugs. Although ATN is common in children of all ages, the glomerular and vascular causes of renal AKI are more common in older children.

Postrenal AKI results from a mechanical or functional obstruction to the flow of urine. The obstruction can be in the lower urinary tract, such as the posterior urethral valves, or bilaterally in the upper tract, such as bilateral ureteropelvic junction obstruction, which is rare. Unilateral obstruction can cause AKI in patients with only a single functioning kidney. Postrenal AKI is more common in newborn babies than it is in older infants.

The most common causes of oliguria and anuria in neonates and children are listed in Table 301-1.

### COMORBID CONDITIONS

Although oliguria and anuria are not uncommon in previously healthy children, about two-thirds of such patients have an underlying comorbid condition. These conditions include the following:

- Neurologic conditions, when the patient has a compromised thirst mechanism or is seriously disabled and thus totally dependent on others for nutrition

and hydration, as may be the case in patients with severe cerebral palsy.

- Renal diseases that impair the ability to maximally concentrate the urine, as may occur with salt-losing nephropathy or chronic renal failure.
- Gastrointestinal conditions that cause hypoalbuminemia and decreased intravascular volume as a result of a low oncotic pressure, as in celiac disease or hepatic failure.
- Endocrine diseases such as diabetes insipidus and diabetes mellitus, which are associated with increased hypotonic urine output and osmolar diuresis, respectively.
- Hematologic conditions such as sickle cell disease or trait, which impair urine concentration mechanism, or oncologic emergencies such as tumor lysis syndrome, which causes renal failure, particularly if the patient is not well hydrated.
- Therapy that may predispose the patient to renal failure (eg, nonsteroidal anti-inflammatory drugs, angiotensin-converting enzyme inhibitors, aminoglycosides, contrast media) because these substances impair renal autoregulation in the presence of mild renal insufficiency or dehydration and may result in oliguria or anuria.

### EVALUATION

#### History

A thorough history and physical examination are important in identifying the cause of oliguria or anuria, which is of particular clinical significance in prerenal and postrenal AKI cases because early diagnosis and prompt treatment often result in quick recovery. A history of vomiting, diarrhea, hemorrhage, sepsis, and decreased oral intake associated with oliguria suggests a prerenal cause. Besides symptoms related to the disease process, such children may exhibit increased

**Table 301-1** Most Common Causes of Oliguria and Anuria

	PRERENAL	RENAL	POSTRENAL
<b>NEONATE</b>	Perinatal asphyxia Respiratory distress syndrome Hemorrhage Sepsis or shock Congenital heart disease Dehydration Drugs (indomethacin, maternal use of ACE inhibitors or NSAIDs)	ATN Exogenous toxins (aminoglycosides, amphotericin B) Endogenous toxins (hemoglobin, myoglobin, uric acid) Congenital kidney diseases Vascular (renal vein thrombosis, renal artery thrombosis)	Posterior urethral valves Meatal stenosis Bilateral ureteral obstruction Neurogenic bladder
<b>CHILDREN</b>	Dehydration Hemorrhage Burns Third-space loss (surgery, trauma, nephrotic syndrome) Renal loss (diabetes mellitus, diabetes insipidus, diuretics) Shock Decreased cardiac output	ATN Glomerulonephritis Exogenous toxins (aminoglycosides, amphotericin B) Endogenous toxins (hemoglobin, myoglobin, uric acid) Vascular (hemolytic uremic syndrome, vasculitis) Interstitial nephritis	Posterior urethral valves Meatal stenosis Bilateral ureteral obstruction Neurogenic bladder Obstructive urinary tract stones or sludge

ATN, acute tubular necrosis; ACE, angiotensin-converting enzyme; NSAIDs, nonsteroidal anti-inflammatory drugs

thirst, palpitations, fatigue, and clinical signs of dehydration, including weight loss. A history of poor urinary stream, dribbling, or enuresis in older children may be the result of urinary tract obstruction. A history of abnormal renal findings during routine antenatal ultrasonography can help diagnose such patients.

A history of gross hematuria or edema strongly suggests intrinsic renal disease. A history of pharyngitis or impetigo a few weeks before the onset of gross hematuria can be the result of postinfectious glomerulonephritis, and bloody diarrhea often precedes hemolytic uremic syndrome. Patients with systemic vasculitis (eg, systemic lupus erythematosus) may have a history of fever, joint pains, and skin rash along with oliguria. A history of recurrent sinusitis or lower respiratory tract infections may suggest Wegener granulomatosis, and hemoptysis may indicate the presence of a pulmonary-renal syndrome, such as Goodpasture syndrome or microscopic polyangiitis. A detailed history of recent or ongoing chronic medications is important to exclude the possibility of interstitial nephritis. In neonates, a history of umbilical artery catheterization favors a diagnosis of renal artery thrombosis. Family history is helpful in diagnosing conditions such as diabetes insipidus and polycystic kidney disease.

### Physical Examination

A comprehensive physical examination is the key to assessing the severity of the disease process and the possible cause of oliguria or anuria. The presence of tachycardia, dry mucous membranes, sunken eyes, orthostatic blood pressure changes, decreased skin turgor, or hypotension indicates hypovolemia, resulting in prerenal oliguria or anuria. A palpable bladder with a weak urine stream or dribbling suggests bladder neck or urethral obstruction. A sacral tuft of hair or myelomeningocele may be associated with neurogenic bladder, which can cause obstructive uropathy with postrenal oliguria or anuria.

Children with intrinsic renal damage are likely to have a circulatory volume overload, and such children may exhibit hypertension, edema, or both. Younger children, particularly infants, may have signs of congestive heart failure, such as hepatomegaly, gallop rhythm, and pulmonary edema. Clinicians need to look closely for specific signs that point to underlying renal disease. These signs may include severe anemia in patients with hemolytic uremic syndrome, a butterfly rash on the face and musculoskeletal involvement in patients with systemic lupus erythematosus, and typical purpuric rash over the buttocks and extensor surface of the lower extremity in Henoch-Schönlein purpura. Abdominal examination may reveal palpable kidney, which may be caused by renal vein thrombosis, polycystic kidney disease, multicystic dysplastic kidney, or hydronephrosis.

### Laboratory Studies

Preexisting risk factors, historical details, and the results of the physical examination will help the physician choose appropriate laboratory tests. Urinalysis is the most important noninvasive diagnostic test. A thorough examination of a freshly voided or bladder-catheterized

urine sample helps distinguish prerenal from renal causes of oliguria or anuria. A normal or near-normal urinalysis, characterized by few cells with little or no casts or proteinuria, is seen in prerenal disease, urinary tract obstruction, and some cases of ATN. A urine sample showing muddy-brown granular casts and epithelial cell casts strongly suggests ATN. The finding of red cell casts is diagnostic of glomerulonephritis, and presence of significant proteinuria indicates glomerular disease.

Urinary indices, including urine sodium, specific gravity, creatinine, and osmolality, are important diagnostic tools for oliguria. The urine sodium concentration is usually above 40 mEq/L in ATN and is below 10 mEq/L in oliguria resulting from intravascular volume depletion. Neonates have decreased ability to conserve sodium, and, as a result, prerenal disease is associated with urine sodium concentration less than 20 to 30 mEq/L. In prerenal oliguria, urine specific gravity is more than 1,020, the ratio of urine to plasma creatinine is more than 40, and the ratio of urinary to plasma osmolality is more than 1.5. In renal causes of oliguria, the ratio of urine to plasma osmolality is less than 1.5, and the ratio of urine to plasma creatinine is less than 20. The effect of variations in urine volume on interpreting these urinary indices is eliminated by calculating fractional excretion of sodium (FENa). A fractional excretion of sodium of less than 1% suggests reabsorption of almost all filtered sodium in response to decreased renal perfusion (prerenal), whereas in ATN the excretion is more than 2%. Newborns and young infants cannot establish a FENa of less than 2%, even in prerenal AKI.

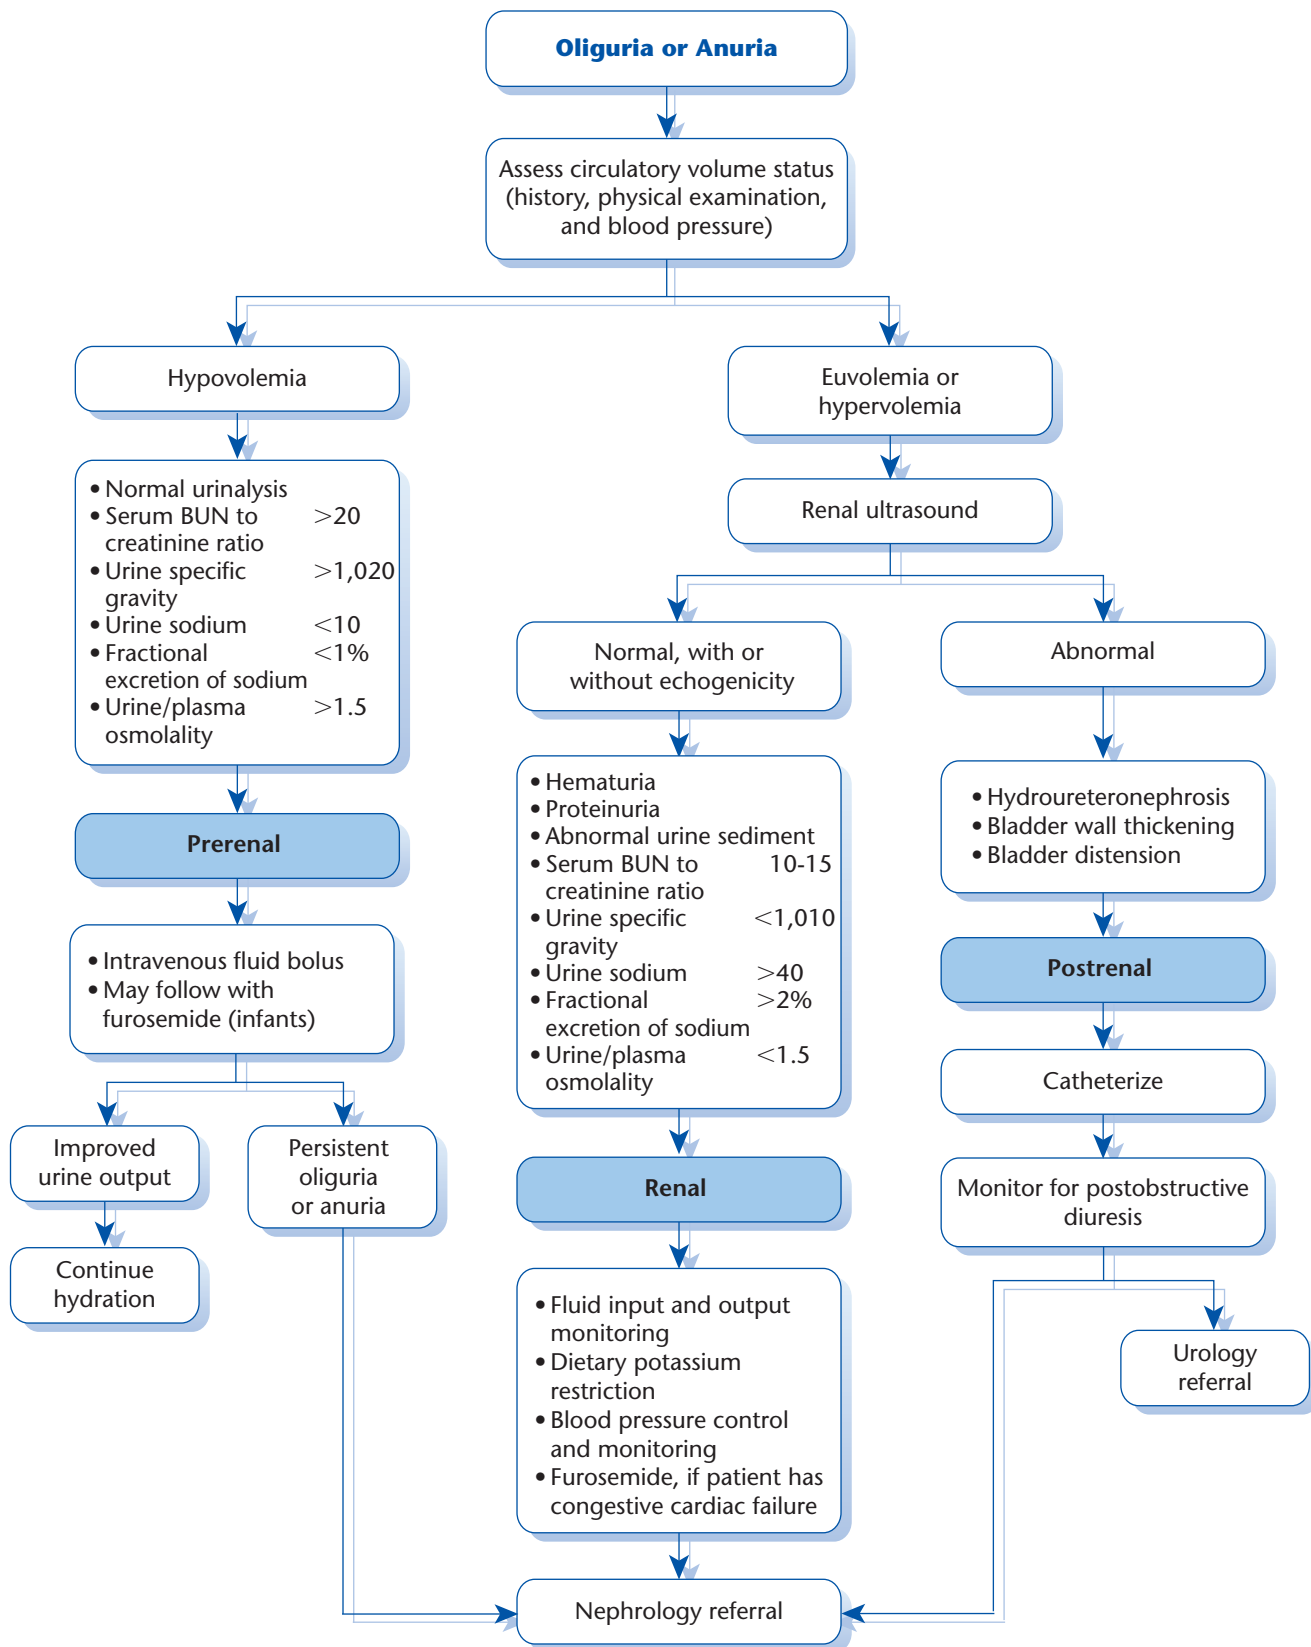

The severity of renal damage or hypoperfusion is also indicated by increased blood urea nitrogen (BUN) and serum creatinine concentrations. In prerenal oliguria, increased BUN is marked, and the ratio of BUN to serum creatinine is more than 20:1, whereas a ratio of 10:1 to 15:1 suggests intrinsic renal damage.

### Imaging Studies

Renal ultrasonography is an important diagnostic tool in patients with oliguria or anuria but is generally not indicated in children with prerenal failure from dehydration who respond promptly to fluid resuscitation. Ultrasonography provides important information regarding kidney size and echogenicity, renal blood flow, collecting system, and urinary bladder. Children with intrinsic causes for oliguria or anuria may have echogenic and slightly enlarged kidneys. An ultrasound examination showing bilateral hydronephrosis or hydroureteronephrosis and bladder wall thickening is consistent with obstruction of the bladder outlet causing postrenal oliguria or anuria. Ultrasonography can also detect congenital renal disorders such as polycystic kidney disease and multicystic dysplastic kidney. Doppler examination of the renal blood flow is helpful in diagnosing renal vascular thrombosis.

## MANAGEMENT

The algorithm for managing patients with oliguria or anuria is shown in Figure 301-1.

**Figure 301-1** Algorithm for management of patients with oliguria or anuria. BUN, blood urea nitrogen.

The key to preventing oliguria or anuria is adequate hydration in at-risk patients. This group may include patients who have just undergone surgery; patients receiving nephrotoxic medications such as amphotericin B, acyclovir, or radiocontrast agent; and patients at risk for developing tumor lysis syndrome or pigment nephropathy caused by hemoglobinuria or myoglobinuria.

The major goal of treatment of prerenal oliguria or anuria is to restore intravascular volume. An estimate of volume status is needed to begin and continue fluid therapy. This amount is assessed by a history and a physical examination that includes assessment of body weight, skin turgor, capillary refill, peripheral edema, and blood pressure. A dehydrated child with oliguria or anuria should receive a fluid bolus of normal saline or Ringer's lactate at 20 mL/kg to restore fluid volume. Depending on the patient's response, another bolus may be needed.

Children with oliguria and volume overload may benefit from furosemide therapy and may require fluid restriction, as well as blood pressure and acid-base monitoring. Children with oliguria that results from obstruction may require urinary catheterization. Relief of obstruction may be followed by postobstructive diuresis and resultant hyponatremia and hypokalemia requiring fluid and electrolyte replacement.

Management of oliguria also includes timely treatment of the underlying etiology: for example, inotropic support in a child with heart failure or shock, appropriate antibiotics in cases of sepsis, and steroids for acute interstitial nephritis and selected cases of glomerulonephritis.

### WHEN TO REFER OR ADMIT

Children should be referred to a nephrologist or admitted to the hospital (or both) if they have any of the following:

- Persistent oliguria or anuria despite an adequate fluid challenge in a dehydrated child
- Persistent oliguria or anuria that continues after removal of the offending nephrotoxins
- Oliguria or anuria associated with swelling, hypertension, gross hematuria, abnormal blood chemistry, and severe systemic signs or symptoms
- Urology referral for oliguria or anuria caused by obstructive uropathy

## Chapter 302

# OPPOSITIONAL DEFIANT DISORDER

Martina B. Albright, PhD; Sophia L. Maurasse, MD;  
J. Stuart Ablon, PhD

## CASE REPORT

Keenan, a 9-year-old African American boy, arrives for his annual well-child with his mother. Keenan lives with his mother, stepfather, and older sister (age 12 years). Keenan's mother is tearful when she describes the calls she has been getting from school in the past few months. Keenan sits quietly on a stool in the office looking uncomfortable as his mother talks. His mother reports he was born 6 weeks early after a complicated pregnancy and was intubated in the first 24 hours after his delivery by cesarean section. He remained in the hospital for 2 weeks with some feeding complications. Keenan's mother describes him as a consistently poor sleeper (often waking during the night). He had severe reflux until age 2 years. However, he met all developmental milestones. He has been healthy since his delivery except for a broken arm from a fall off a bike.

Keenan's mother reports he has always been a challenging child. She states, "Nothing is ever easy with him. I am worn out." At home, she is never sure whether he will do what she asks of him. "Some days it seems all he does is argue with us about everything." He often says no when asked to turn off the TV, set the dinner table, or get ready for school or sports practice, and has started to swear at her. Recently he said to his mother, "You think I am a bad kid. You hate me." He frequently blames his sister or the "stupid kids at school" or his "dumb teacher" for anything that doesn't go well.

Until this year it was mostly at home that Keenan was hard to manage. He is now in the fourth grade, and his school is concerned about him. In the past, his teachers often described him as a "handful" or needing to be better at listening but as an enthusiastic member of the class. He is a good athlete and enjoys sports, but now with competitive sports he is often described as being a poor sport and at times rude to his coaches. This year at his midyear report his teachers described him as unpredictable, lacking effort, disruptive and silly, often uncooperative, and just not interested in applying himself. He is academically performing at grade level but "acts up" when asked to complete reading or writing projects.

On physical examination, Keenan is in the 50th percentile for height, weight, and head circumference. His vital signs and vision and hearing screening findings are normal. His tonsils and adenoids seem large. He has no dysmorphic features, and his physical appearance is normal. He is taking no medications. Keenan's mother reports he has a cousin who was expelled for behavioral issues related to attention-deficit/hyperactivity disorder (ADHD) and an aunt

with depression and alcohol addiction. Keenan is well dressed, articulate, and sullen but cooperative in the office, admitting he gets really mad sometimes because other people “can be real jerks.”

## DEFINITION

The case of Keenan demonstrates one of the frequently occurring presentations to pediatric primary care offices: the elementary school child with acting-out behavior of unclear origin. Oppositional defiant disorder (ODD) under the classification of disruptive, impulse control, and conduct disorders, encompasses a broad range of acting-out behavior toward parents or teachers. It is one of the most commonly encountered clinical disorders in children ranging from preschoolers through teenagers.

The pediatrician is usually alerted when problems with compliance, negative and hostile behavior, and other forms of aggression such as verbal threats and physical acts create a significantly problematic disruption in social, academic, or family functioning. According to the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5), the indications of ODD are a pattern of angry or irritable mood, argumentative or defiant behavior, or vindictiveness lasting at least 6 months and exhibited in interactions with someone other than a sibling, leading to poor functioning in school, at home, or in both locations. As seen in the case of Keenan, it is typical that a parent

reports having longstanding struggles with the child that finally become intolerable when school or the community begins to experience the same challenging behavior. The criteria for diagnosing ODD are described in Box 302-1.

## PREVALENCE

A review of epidemiologic studies according to age, gender, socioeconomic status, neighborhood, and urban or rural life estimates that the prevalence of ODD is from 2% to 16% in preschool- and school-aged children. The community prevalence of the disorder is reported as widely ranging, depending on which assessment methods, time frame, definition of diagnosis, and number of participants are used. Prevalence in preschoolers has received particular focus in the past decade because there is increasing evidence that treatments for disruptive behavior disorders (DBDs) identified in early childhood are effective. In one epidemiologic study of preschoolers, a prevalence rate of 6.6% for ODD was noted.

## By Age

Rates of ODD remain relatively constant from age 5 until age 10 years, then begin to decline for both boys and girls. However, if one disregards overlap with conduct disorder (CD), clinically significant levels of oppositionality seem to persist well beyond childhood. According to a large review of the literature on ODD,

### BOX 302-1 DSM-5 Diagnostic Criteria for Oppositional Defiant Disorder

- A. A pattern of angry or irritable mood, argumentative or defiant behavior, or vindictiveness lasting at least 6 months as evidenced by at least 4 symptoms from any of the following categories, and exhibited during interaction with at least 1 individual who is not a sibling.

#### ANGRY OR IRRITABLE MOOD

1. Often loses temper
2. Is often touchy or easily annoyed
3. Is often angry and resentful

#### ARGUMENTATIVE OR DEFIANT BEHAVIOR

4. Often argues with authority figures or, for children and adolescents, with adults
5. Often actively defies or refuses to comply with requests from authority figures or with rules
6. Often deliberately annoys others
7. Often blames others for his or her mistakes or misbehavior

#### VINDICTIVENESS

8. Has been spiteful or vindictive at least twice within the past 6 months

**Note:** The persistence and frequency of these behaviors should be used to distinguish a behavior that is within normal limits from a behavior that is symptomatic. For children younger than 5 years, the behavior

should occur on most days for a period of at least 6 months unless otherwise noted (criterion A8). For individuals 5 years or older, the behavior should occur at least once per week for at least 6 months unless otherwise noted (criterion A8). Although these frequency criteria provide guidance on a minimal level of frequency to define symptoms, other factors should also be considered, such as whether the frequency and intensity of the behaviors are outside a range that is normative for the individual's developmental level, gender, and culture.

- B. The disturbance in behavior is associated with distress in the individual or others in his or her immediate social context (eg, family, peer group, work colleagues), or it has a negative effect on social, educational, occupational, or other important areas of functioning.
- C. The behaviors do not occur exclusively during the course of a psychotic, substance use, depressive, or bipolar disorder. Also, the criteria are not met for disruptive mood dysregulation disorder.

*Specify current severity:*

**Mild:** Symptoms are confined to only 1 setting (eg, at home, at school, at work, with peers).

**Moderate:** Some symptoms are present in at least 2 settings.

**Severe:** Some symptoms are present in 3 or more settings.

no firm conclusion can be reached regarding the prevalence of ODD as a function of age. Thus, rates of ODD across childhood and adolescence indicate the complex developmental trends within the disorder. The diagnosis of ODD is relatively stable over time, but most affected children (approximately 67%) will no longer meet criteria after 3-year follow-up. Earlier age at onset of ODD symptoms conveys a poorer prognosis in terms of progression to CD. Those who have early-onset ODD (before age 8 years) have a threefold increase in CD.

### By Socioeconomic Status

Oppositional defiant disorder, like CD, is more prevalent among children and teens from families of low socioeconomic status. A 2009 study in an urban community sample found ODD to occur in 13.4% of the population of preschoolers. Neighborhoods characterized by high crime rates, social disorganization, and more untreated parental psychopathology also seem connected to higher rates of ODD.

### By Gender

Oppositional defiant disorder is more common in boys than girls, but the data are inconsistent. Gender differences do not emerge until after age 6 years, when boys show more forms of disruptive behavior. There are many more school-aged boys diagnosed with ODD than there are school-aged girls. One hypothesis is that the developmental progression for boys may be toward emergent CD, whereas for girls the trajectory may be toward developing internalizing disorders such as depression. Another explanation for the gender difference is that parents report equal prevalence of ODD in boys and girls, but teachers report significantly more ODD in boys than girls, presumably because acting-out behavior at school draws more attention. By adolescence, the prevalence of ODD in girls and boys is equivalent.

## ETIOLOGY

Etiologic research on ODD tends to be intertwined with research on CD. Most children diagnosed with CD exhibit the behaviors associated with ODD concurrently or at an earlier age. Therefore, to the extent that the behaviors associated with ODD often precede the more serious forms of psychopathology, including not only CD but also adult antisocial personality disorder, the presentation of these behaviors represents an important window of opportunity for prevention efforts. However, the continuity between ODD and CD is not an absolute: approximately two-thirds of children diagnosed with ODD do *not* subsequently develop CD. The behaviors associated with ODD have nonetheless been shown to have potent and negative effects on child–adult and child–peer interactions. Most researchers conclude that there is no single cause or main effects model to explain the complexity of the symptoms that make up ODD. The most widely accepted opinion is that ODD occurs from a complex mix of risk and protective factors found in the biopsychosocial makeup of the individual.

### Biologic Factors

Many authorities think that biology plays an important role in ODD because there is familial clustering of

certain DBDs such as ADHD as well as substance use and mood disorders. Studies of the genetics of ODD have produced mixed results. Recently, researchers have found that mother, father, and teacher reports all point to the influence of additive genetic factors in both boys and girls. ODD appears more in families in which at least 1 parent has a history of a mood disorder, ODD, CD, ADHD, antisocial personality disorder, or a substance-related disorder. In addition, some studies find mothers with depression are more likely to have children with oppositional behavior. It is probable that the joint influence of environment and biology, as in many disorders, plays a role.

Temperamental factors have been implicated in the future development of disruptive behavior. Baseline underarousal has also been found in children with ODD. A compilation of biologic factors such as exposure to toxins, exposure to nicotine in utero, and deficient nutrition all may have effects but are highly inconsistent. Neurobiologic theories have been explored in the etiology of aggression. The role in aggression of neurotransmitters such as serotonin, norepinephrine, and dopamine has been investigated, but no single pathway has been identified as the root cause. ODD is clearly familial, but research has yet to determine what role genetics play.

### Psychological Factors

Some researchers suggest that children with ODD present similarly to children with poor attachment, and that oppositional behavior is a signal to an unresponsive parent. Another line of research has focused on children's deficient social information processing. Aggressive children underuse pertinent social clues, misconstrue hostile intent by peers, and are poor problem solvers. The most prevalent explanation of psychological factors leading to ODD is the coercion or social interactional model. Most representations of this model focus on patterns of parental discipline that contribute to the development of coercive parent–child exchanges.

In addition to the coercion model, more recently alternative conceptualizations of ODD have been proposed. Developmental theorists have long underscored the importance of affective modulation and self-regulation. In keeping with these ideas, an explanation has been proposed that suggests children with ODD suffer from poor self and emotional regulation skills along with various other delays in cognitive areas. Noncompliance is a hallmark behavior in the development of conduct problems. The skill of *compliance*, defined as the capacity to defer or delay one's own goals in response to the imposed goals or standards of an authority figure, can be considered one of many developmental expressions of a young child's evolving capacities in the domains of adaptation, self-regulation, and affective modulation.

## DIAGNOSIS

### Signs and Symptoms

The first symptoms of ODD may be evident during the preschool years and rarely later than adolescence. (Note that diagnosing a preschooler with ODD requires

awareness of what is within normal limits for this young age and what may truly be symptomatic. See Box 302-1.) Onset is typically gradual, occurring over the course of months or years. The negative, hostile behaviors associated with ODD are almost always present in the home and with individuals the child knows well and often occur simultaneously with poor self-esteem, mood lability, and low frustration tolerance.

The diagnosis of ODD can be made most readily from a detailed description of a child's life at home and at school. Currently, there is no biologic marker or specific diagnostic test that reliably identifies ODD in a child or teen.

In clinical practice the greatest challenge is to determine whether there is an underlying medical or psychological condition that could better explain ODD symptoms. All children are defiant at times, especially in early childhood and during adolescence. Determining when parent report, teacher report, direct observation, and the child's own description warrant treatment is dependent on the degree of interference the oppositionality creates within family, school life, and friendships. In making this determination, one area of consideration is the level of punitive discipline at home. Parental physical aggression can be associated with aggressive child behavior. Many studies cite hyperactivity, aggression, and oppositional behavior as all related to elevated levels of punitive discipline and spanking. Thus, children who experience punitive discipline, spanking, and physical aggression show a pattern of increasing severity in the problems they display.

Assessing a child or adolescent with significant hostile or negative behaviors involves more than simply assessing the type, rate, or severity of the child's behavior problems and should involve assessing the many risk factors that can play a role in development of ODD or CD across these pathways. Measures that may be helpful in determining an ODD diagnosis are suggested later in this chapter under Evaluation.

### Differential Diagnosis

Because there are no definitive biologic or imaging markers for ODD, a diagnosis of ODD requires evaluating whether the child meets *DSM-5* criteria (see Box 302-1) and deciding whether any other factors exist that may better explain a child's challenging behavior. The behaviors associated with ODD (temper outbursts, persistent stubbornness, resistance to directions, unwillingness to compromise, unwillingness to give in or negotiate, deliberate annoyance of others, blaming others for one's own mistakes, and verbal and minor physical aggression) can be because of a medical, psychosocial, psychiatric, or neurologic condition. Conditions that may mimic or co-occur with ODD during childhood and adolescence are given in Box 302-2.

Deciding whether these issues are the primary cause of the child's challenging behavior or whether they coexist with ODD is central to treatment. Although mental health physicians, nonphysician clinicians, and educators can assist in identifying mental health and educational disorders, the role of the

primary care physician is crucial in ruling out a medical condition.

There are some noted medical complications that may present with ODD-like symptoms. Many research studies find that obstructive sleep apnea (OSA) is correlated with cognitive challenges. Children who are chronically sleep deprived from OSA may have behavioral, mood, learning, and attention problems that mimic symptoms of ADHD and related learning and disruptive behavior disorders. Alternatively, what might look like a behavioral issue could actually be a sign of hearing loss or even a vision problem. Children who cannot hear or see properly cannot pay attention in class. In addition, medication side effects may explain irritability and oppositionality. Many neurologic disorders can cause learning challenges and disruptive behavior in children as well.

### Coexisting Conditions

ODD is frequently comorbid with other psychiatric disorders and often precedes the development of CD, substance abuse, and severe delinquent behavior. The overlap between ODD and CD warrants careful discussion and may require the assistance of a mental health specialist to determine. The *DSM-5* precludes a diagnosis of ODD in children who meet criteria for CD, so many clinically significant oppositional behaviors are overshadowed by a diagnosis of CD. If the CD exclusion is dropped, data suggest that levels of oppositional behavior severe enough to meet criteria for a disorder persist at essentially the same levels from early childhood to middle adolescence. This suggests that finding a treatment for noncompliance is no less important in older than in younger age groups, even though the noncompliance may be overshadowed by the more severe issues of CD.

There have been continuing debates over the nature of the connection between the angry-irritable mood symptoms and negative, disobedient, and hostile behavior patterns indexed by ODD, and the rule violations and physical aggression more characteristic of CD. Many studies have combined the 2 terms together under DBD, making the significance and role of ODD difficult to understand. Some researchers have asked, Is ODD a precursor to CD or a milder version of essentially the same disorder, or does it embody a somewhat different clinical construct? Three observations have been made. First, if the 2 disorders are assessed independently, each disorder shows quite distinct age profiles. Rates of ODD remain stable from latency through mid-adolescence, whereas rates of CD increase in the teen years. Second, most children with CD also showed high amounts of oppositionality, and this did not change with age. And third, when comorbidity was evaluated with other disorders, both ADHD and anxiety disorders seemed more strongly linked with ODD than with CD symptoms, though depression did not.

Recent research looking at phenotype and causal structure of CD has shown that CD and ODD share half their genetic influences, but their genetic etiologies are distinct in other ways. Unlike most other dimensions of psychopathology, half the genetic influences of CD seem to be unique to CD. In contrast,

**BOX 302-2 Conditions That May Mimic or Co-occur With Oppositional Defiant Disorder (ODD)**

- *Attention-deficit/hyperactivity disorder (ADHD).* This is a common comorbidity. Association of ODD and ADHD confers a poorer prognosis, and children tend to be more aggressive, have more behavior problems that are more persistent, suffer peer rejection at higher levels, and have more significant academic underachievement. See Chapter 168, Inattention and Impulsivity, and Chapter 220, Attention-deficit/Hyperactivity Disorder.
- *Sleep deprivation.* Sleep problems can cause irritability and contribute to outbursts of anger and poor impulse control.
- *Learning problems or disabilities.* Unidentified learning difficulties can contribute to frustration and oppositionality. If disruptive or aggressive behavior is associated with problems of school performance, the child may have a learning disability. See Chapter 172, Learning Difficulty, to explore this possibility.
- *Developmental problems.* Children with overall intellectual or social limitations may experience frustration and poor impulse control, or academically gifted children may find academic placement unstimulating and may exhibit disruptive behavior (persistently annoying and distracting others, refusing to comply with teachers' requests) as a result.
- *Exposure to adverse childhood experiences (ACEs).* Children who have experienced or witnessed trauma, violence, a natural disaster, separation from a parent, parental divorce or separation, parental substance use, neglect, or physical, emotional, or sexual abuse are at high risk for developing emotional difficulties such as adjustment disorder or post-traumatic stress disorder (PTSD) and may manifest outbursts of disruptive or aggressive behavior; this possibility should always be borne in mind because PTSD requires specific trauma-focused interventions. The physician should tactfully explore the possibility that harsh physical or emotional punishment is related to the child's behavior problem or that tensions might escalate to that point. Denial of trauma symptoms does not mean trauma did not occur; questions about ACEs should be repeated as a trusting relationship is established.
- *Bereavement.* Most children will experience the death of a family member or friend sometime in their childhood. Other losses may also trigger grief responses, including separation or divorce of parents, relocation, change of school, deployment of a parent in military service, breakup with a girlfriend or boyfriend, or remarriage of a parent. Such losses are traumatic. They may result in feelings of sadness, despair, insecurity, anger, or anxiety immediately following the loss and, in some instances, more persistent anxiety or mood problems, including PTSD or depression. In some children, such losses trigger aggressive or disruptive behavior. See also Chapter 129, Anxiety, and Chapter 137, Depression.
- *Anxiety.* Many children with disruptive or aggressive behaviors have anxiety. When faced with demands that make them anxious, they use oppositional behavior to manage their anxiety or avoid the expectations that triggered their anxiety. See Chapter 129, Anxiety.
- *Depression or bipolar disorder.* Marked sleep disturbance, disturbed appetite, irritability, low mood, or tearfulness could indicate that a child is depressed. Symptoms of depression rapidly alternating with cycles of agitation may suggest bipolar mood disorder. Common symptoms of pediatric bipolar disorder include explosive or destructive tantrums, dangerous or hypersexual behavior, aggression, irritability, bossiness with adults, driven creativity (sometimes depicting graphic violence), excessive talking, separation anxiety, chronic depression, sleep disturbance, delusions, hallucinations, psychosis, and talk of homicide or suicide.
- *Substance use.* All children exhibiting disruptive or aggressive behavior should be screened for substance use and abuse because drug effects, or withdrawal from drugs, may cause irritability and reduced self-control.
- *Autism spectrum disorders.* Children with this developmental pattern also have problems with social relatedness (eg, poor eye contact, preference for solitary activities), language (often stilted), and range of interest (persistent and intense interest in a particular activity or subject). They often have very rigid expectations for routines or parent promises and become anxious or angry if these expectations are not met.

ODD broadly shares nearly all of its genetic influences with other disorders and has little genetic variance. This finding further supports that CD is a relatively distinct syndrome at both the phenotypic and etiologic levels.

Most children meeting criteria for CD also meet DSM-5 criteria for ADHD and ODD. Importantly, however, only one-third of youth diagnosed with ODD ultimately meet criteria for CD. The most common coexisting condition is ADHD, and the continuity between ODD and ADHD has been well established. Current data show that approximately 65% of children diagnosed with ADHD meet criteria for comorbid ODD and that more than 80% diagnosed with ODD meet criteria for comorbid ADHD. Researchers

have examined the course of ODD in girls with ADHD. At 5-year follow-up (in adolescence), results indicated that ODD at baseline predicted increased risk for ODD and major depression at follow-up, beyond the risk for ADHD alone. The risk for CD was 24% in subjects with ADHD plus ODD versus 10% in subjects with ADHD alone.

The continuity between ODD and mood and anxiety disorders has been increasingly documented. Researchers have shown high rates of ODD in children diagnosed with depression and bipolar disorder. In one study, nearly 70% of children diagnosed with severe depression and 85% of children diagnosed with bipolar disorder were also diagnosed with ODD. In fact, it is children with ODD with comorbid mood

disorders who are at heightened risk for the development of CD. Meaningful rates of anxiety have been found in children with ODD. For example, one study found that more than 60% of youth diagnosed with ODD had comorbid anxiety disorder and 45% of children diagnosed with anxiety disorder had comorbid ODD.

When evaluating severe symptoms of ODD that do not improve with initial psychosocial interventions, or the possibility of comorbid disorders, a child psychiatrist or specialist should be consulted to rule out the possibility of other disorders and assess and monitor potential need for level 2 medications (which include antipsychotics or lithium, described in Chapter 62, Psychotropic Medications in Primary Care Pediatrics). Group 2 medications can be monitored in primary care settings, but because they generally have a more serious safety profile or more complicated monitoring requirements than group 1 medications, they are generally prescribed by specialists, including child psychiatrists, developmental-behavioral pediatricians, specialists in neurodevelopmental disabilities or adolescent medicine, pediatric neurologists, and adult psychiatrists with additional training in adolescent psychiatry.

### Laboratory and Imaging Studies

There are no specific laboratory or imaging studies used to make the diagnosis of ODD. However, besides a thorough psychiatric interview with parents and child, along with diagnostic measures from teachers, it is important to note that visits to the child's pediatrician have occurred regularly and no possible medical complications are identified.

### Evaluation

Children who present with disruptive or aggressive behaviors should be considered carefully if these behaviors are persistent (lasting more than 6 months). If left untreated the child will have an increased risk for school failure, difficulty with the legal system, underemployment, substance abuse, and antisocial personality disorder.

How do you evaluate a child when ODD is a possibility? If ODD is viewed as poor compatibility between child and adult, truly understanding the areas of incompatibility that give rise to oppositional behavior requires an understanding of both the child and adult.

As mentioned previously, often a mental health physician or nonphysician clinician is helpful in making a diagnosis of ODD; however, the primary care physician can rely on the specific guidelines described in this chapter to conduct an initial assessment independently.

An *assessment* can be defined as the identification and understanding of compatibility and incompatibility between a child and given aspects of his or her environment and the contributing factors to these conditions. A variety of assessment elements are considered to be useful. A *situational analysis* provides indispensable information about the child, adult, and environmental details contributing to oppositional moments and the incompatibility that gives rise to

such exchanges. In other words, with whom (mother, father, peer, baseball coach, piano teacher) is the child interacting when the oppositional episodes occur? What are the cognitive demands or expectations precipitating oppositional episodes and how is this understood in terms of compatibility? What are the specific antecedents, triggers, or conditions under which the behavior occurs? A *developmental history* that asks about early temperament, trauma history, attachment history, and family history is informative. A *school history* that asks about the child's academic as well as social-emotional presentation helps to inform the physician about the situational specificity of the behaviors. A *treatment history* including previously implemented medical and nonmedical interventions and their effectiveness is useful. If the belief is that oppositional behavior is resulting from lagging skills on the part of the child and incompatibility in the interaction between adult and child, formal and informal assessment is invaluable in the domains of general cognitive skills, attention and working memory skills, language processing skills, social skills, and problem-solving skills. Some formal assessment measures useful when considering a diagnosis of ODD are listed in Box 302-3. It is important to obtain both parent and teacher ratings of the child to determine behavior in 2 contexts; often a child will seem challenging in one setting, but not the other.

### Importance of Early Diagnosis and Intervention

Early-onset oppositional and aggressive behavior in preschoolers is problematic for parents and a known precursor of more serious and costly antisocial behaviors such as delinquency and substance abuse that may persist into adolescence and adulthood. Young children with disruptive behaviors are at risk for peer rejections, school absences, and academic problems such as underachievement and school dropout.

The underlying reasons for the unique features of ODD development remain unclear. Recent findings suggest that youth oppositionality involves distinct dimensions, each differentially predicting other psychopathology: an irritable dimension predicting depression and generalized anxiety disorder (GAD), a headstrong dimension as a predictor of ADHD and nonaggressive CD, and a hurtful dimension predicting aggressive CD. Researchers point out that referral rates among preschool populations are much lower than prevalence rates of ODD, and therefore primary care physicians need to be alert to opportunities for early detection and interventions for preschoolers especially, because efficacious treatments exist.

## MANAGEMENT

When a pediatrician uses the previously described assessment methods to confirm a possible diagnosis of ODD, a referral to a mental health physician or nonphysician clinician is the next step; however, the most effective treatment model is comanagement in which the pediatrician maintains contact with the mental health specialist and the family throughout the process. The pediatrician has a longer relationship with

**BOX 302-3 Assessment Measures**

- **Connors Rating Scale**
- **SNAP-IV**
- **The Eyberg Child Behavior Inventory (ECBI)**
- **Child Behavior Checklist (CBC)**
- **Pediatric Symptom Checklist (PSC)**
- **The Child Symptom Inventory—Parent**
- **Thinking Skills Inventory** ([www.thinkkids.org](http://www.thinkkids.org))
- **The AAP Task Force on Mental Health** has provided toolkits for helping manage mental health concerns such as ODD ([www2.aap.org/compmpeds/doch/mentalhealth/](http://www2.aap.org/compmpeds/doch/mentalhealth/)).
- **Vanderbilt Assessment Scale: Parent Assessment Scale and Teacher Assessment Scale** (AAP Toolkit) This tool has been developed for children 6 to 12 years of age.
- **Modified Overt Aggression Scale (MOAS)** (AAP Toolkit): This tool was developed for adults but has been used with adolescents.
- **Strengths and Difficulties Questionnaire (SQD)**: also gives indication of ODD.
- **Straight Talk About Psychological Testing for Kids**: This book explains how formal neuropsychological testing can be useful when there is a concern about attention or learning challenges. (Braaten E, Felopulos G. The Guilford Press, 2003.)
- **Bright Futures in Practice: Mental Health** has published an array of tools for the early identification of behavioral problems. This site also breaks down normative behavior by developmental stage, which is helpful to review when determining whether behavior is normative ([www.brightfutures.org/mentalhealth/pdf/bridges/oppositional.pdf](http://www.brightfutures.org/mentalhealth/pdf/bridges/oppositional.pdf)).

See Tools for Practice for where to obtain assessments.

the family and will continue to be involved with the child after the conclusion of work with a mental health specialist; thus, comanagement has significant advantages for treatment adherence and continuity. Contact with the child's school may be led by the mental health physician or nonphysician clinician while collaborating with the pediatrician.

### Best Treatment Approaches

ODD is best addressed from a team approach. For best results the child and family must be engaged in the care. Parents are crucial partners in treatment because they need to implement changes at home. How a parent understands the reasons his or her child is acting in a negative, hostile, maladaptive way has an effect on the choice of an intervention. In addition to parents, teachers spend the most time with a child and need to be involved with understanding and treating a child with ODD. Books and Web sites (listed in Tools for Practice) are good ways to engage and begin to inform parents and teachers about ODD.

Some initial interventions are highlighted by the AAP to try before a more formal treatment: Promote daily positive joint activities between parents and child or teen; encourage parents to focus on prevention such as removing activities or avoiding situations that lead to challenging behaviors; encourage parents to be calm and consistent and create a safety and emergency plan.

If a child needs to be referred for formal treatment, however, a range of treatment options are available. Treatment strategies include behavioral programs for both home and school as well as consideration of medication for comorbid mood disorder, anxiety, or impulsiveness. (See Chapter 62, Psychotropic Medications in Primary Care Pediatrics, and descriptions of medication levels 1, 2, and 3.) Symptoms of disruptive behavior and aggression commonly present

to pediatricians and may require comanagement with a mental health specialist because there is considerable controversy regarding whether medication, targeted at aggression or disruptive behavior only, is an appropriate part of a comprehensive treatment plan. Specifically, the AAP lists the following options under the category of “best support” (indicative of being subjected to rigorous randomized controlled trials): anger control, assertiveness training, cognitive behavioral therapy (CBT), multisystemic therapy (MST), parent management training (PMT), and problem-solving social skills. Although not indicated as “best support” in the AAP guidelines, an additional evidence-based model called *collaborative problem solving* (CPS) is offered.

### Specific Psychosocial Treatment Options

Diverse psychosocial treatments have been applied to children's ODD-related behaviors. The treatments can be classified according to focus on parent, child, or systemic characteristics. Generally, parent training models are designed to improve the coercive interactions between parents and their children. Parent training focuses primarily on a variety of patterns of parental discipline that contribute to the development of oppositional behavior and problematic parent-child exchanges. Skills that are typically taught to parents in such models include positive attending, use of appropriate commands, contingent attention and reinforcement, and use of the time-out procedure. Research has documented the efficacy of these procedures. MST is based on a social-ecological model that treats children by reaching out to multiple layers of the child's social environment including family, neighborhood, peers, and school. CBT for children with ODD targets maladaptive social-cognitive processes and focuses on improving anger control, social skills, and problem-solving skills.

Frequently, aspects of these various approaches are combined into a multifaceted intervention program

that targets both parenting skills and children's social skills. The combined programs have produced reductions in children's conduct problems and aggressive behavior and increases in problem-solving and social cognitive skills. An extensive review by Eyberg and colleagues of treatments for disruptive disorders did not reveal a single best intervention. The study suggests parent training as a first-line approach for younger children and reserves direct skills training approaches for older children.

The 2008 Eyberg Review identified 16 evidence-based psychosocial treatments (EBTs). Seven of these are considered "best support" for ODD on the AAP site and described by Eyberg as "probably efficacious." The final treatment option is collaborative problem solving; although not in the Eyberg review, it offers successful treatment of ODD. (See Box 302-4 and Table 302-1 for descriptions and examples of these treatments.)

### Medication

Effective treatment of ODD entails a multimodal approach in which psychosocial interventions are first line and pharmacotherapy is considered when there are comorbid conditions or initial interventions fail to address symptoms such as severe aggression. There is no single drug or regimen indicated for core symptoms of ODD; when pharmacotherapy is considered, comanagement by pediatricians and caregivers involved in implementing psychosocial interventions is important. A wide variety of medications have been tried in different groups with ODD, often comorbid with ADHD or other conditions. These medications include both level 1 medicines (described in Chapter 62, Psychotropic Medications in Primary Care Pediatrics, as those that would be prescribed and monitored by primary care physicians, including stimulants and  $\alpha$ -adrenergic agonists) as well as level 2 medicines that would be prescribed by a specialist such as a child psychiatrist.

ODD symptoms often improve with appropriate treatment of the comorbid conditions. Because comorbidity is the rule rather than the exception in the assessment and treatment of ODD, physicians must remain vigilant after the initial evaluation in detecting, monitoring, and treating commonly comorbid disorders such as ADHD, anxiety, and tic and mood disorders. The choice of regimen is based not only on the presentation of the child but also on reports from caregivers and teachers that are often discrepant in the severity of symptoms. It is crucial that the baseline behavior is understood as accurately as possible because improvement in symptoms may inappropriately be attributed to medications instead of the stabilization in the child's environment. If ODD is comorbid with ADHD and ameliorated with the regimen within the level 1 drugs, the treatment team may not necessarily need a child psychiatrist for ongoing comanagement because the pediatrician can follow level 1 medications while the psychologist and educators, along with parents, can address the psychosocial interventions.

### Stimulants, Atomoxetine, and $\alpha$ -Adrenergic Agonists

The stimulants methylphenidate and amphetamine are considered first-line treatment of ADHD. Given the

high rate of comorbidity of ADHD and ODD, stimulants (commonly methylphenidate) are considered even when oppositionality and aggression are present (see Chapter 62, Psychotropic Medications in Primary Care Pediatrics, and Chapter 220, Attention-deficit/Hyperactivity Disorder, for more detailed discussion of stimulants and treatment of ADHD). An amphetamine should be considered instead if the initial trial fails to provide adequate improvement in symptoms. This may be a worthwhile consideration because some results have suggested that methylphenidate may not have the same effect on some domains of ADHD in patients who also have ODD.  $\alpha$ -Adrenergic agonists, including clonidine and guanfacine, are second-line treatment for ADHD. They are level 1 medications that may be used initially when ADHD, ODD, and tic disorders are comorbid;  $\alpha$ -adrenergic agonists are also considered if stimulants or atomoxetine, a level 2 medication, are not helpful. Both ADHD and ODD symptoms improve with appropriate treatment of ADHD; therefore, optimization of the ADHD regimen would be the initial step.

When ODD does not improve with initial psychosocial interventions or reflects comorbidity with other disorders not yet identified or properly treated with level 1 medications, a child psychiatrist should be consulted to rule out the possibility of other disorders and to assess and monitor potential need for level 2 medications (including atomoxetine, antipsychotics, mood stabilizers, and certain antidepressants, discussed in Chapter 62, Psychotropic Medications in Primary Care Pediatrics). Stimulants remain first-line treatment of ADHD even when aggressive and disruptive behaviors are present and should be considered before the addition of another agent. Atomoxetine is a potent selective norepinephrine reuptake inhibitor used in the treatment of ADHD. When anxiety and a tic disorder are comorbid with ADHD and ODD, consider a trial of atomoxetine first; if not effective, a stimulant may be used. Atomoxetine was found to be as effective in treating ADHD symptoms regardless of the presence of ODD as a comorbid disorder. However, improvement in ADHD as well as ODD symptoms is achieved at higher doses and over a longer duration than would be required in addressing ADHD not comorbid with ODD. Although atomoxetine is well tolerated, a slower rate of titration is associated with improved tolerability, especially because target doses may need to be higher.

Polypharmacy is not unusual in treating the comorbidities of ODD and requires pediatricians and psychiatrists working in concert with other caregivers to optimize the pharmacologic intervention within a comprehensive treatment program.

### Risks of Not Treating

Treatment with psychotherapy is preferable to treatment with medication in children and teens. However, because it is estimated that up to 60% of patients with ODD go on to develop CD, there is a significant need for early identification and intervention through psychotherapy and if necessary through medication to treat mood, anxiety, or impulsiveness.

**BOX 302-4 Evidence-Based Psychosocial Treatments**

- *Anger control training* is a cognitive behavioral therapy-style treatment for elementary school-aged children based on the social information processing model of anger control. Children meet 1 time a week in groups of 6, usually during the school day. Children discuss vignettes of social encounters with peers and possible social cues and motives of individuals in the vignettes. The focus of the work is learning to increase awareness of feelings and to problem-solve through practice in situations designed to arouse their anger.
- *Group assertiveness training* is based on the verbal response model of assertiveness and was conducted with African American eighth and ninth graders. The group treatments, led by either a peer or counselor, both involve 8 hours of assertiveness training with treatment groups of 6 adolescents meeting twice a week for 4 weeks. This treatment is not widely cited but did meet evidence-based psychosocial treatment standards in Eyberg's 2008 review and was designated by the AAP with "best support."
- *Multisystemic therapy (MIS) (MST)* is an intensive family- and community-based treatment that addresses the externalizing behaviors of youth displaying emotional and behavioral disturbances. It is a therapeutic process that provides on average 50 hours of direct family-based treatment over a 4- to 6-month period. A pragmatic and goal-oriented treatment, MST specifically targets those factors in each youth's social network that are contributing to his or her problematic behavior. Thus, MST interventions are delivered in the natural environment and typically aim to develop youth competence by improving the relationships, interactions, and skills of those who surround the youth, especially family members. MST is provided using a home-based model of services delivery targeting children and adolescents ages 12 to 17 years at high risk of out-of-home placement and their families. Therapists work nontraditional hours and are on call for their families 7 days per week around the clock.
- *PMT (also called parent training or behavior management training)* strategies are well established in helping children with oppositional defiant disorder. A mental health physician helps the parents develop skills that will allow them to parent in a way that is more positive and less frustrating. Treatment sessions include instruction in social learning principles and techniques. The therapist provides an overview of underlying concepts, models the technique, and coaches parents implementing the procedures. Procedures and interaction patterns practiced in the sessions are then used at home. Parents are usually taught how to define, observe, and record behavior at the beginning of treatment because after behaviors (eg, fighting, tantrums) are defined concretely, reinforcement and punishment techniques can be applied. Reinforcement for prosocial and nondeviant behavior is central to treatment.
- *Parent-child interaction therapy (PCIT)* is an evidence-based treatment for families with children 2 to 6 years old. PCIT uses 2 phases of training: child-directed interaction, in which parents are trained in nondirective play skills to alter the quality of parent-child interactions, and parent-directed interaction, which focuses on improving parenting skills by teaching parents to give clear instructions, offer praise for compliance, and administer time-out for noncompliance. During PCIT, therapists actively coach parents while they interact with their children. As a result, parents learn more effective parenting techniques, the quality of the parent-child relationship improves, and problem behaviors decrease. Sessions are 1 time per week for an average of 12 to 16 weeks.
- *Problem-solving skills training (PSST)* is a behavioral treatment designed for children ages 7 to 13 years with disruptive behavior. Children are taught problem-solving strategies and encouraged to generalize these strategies to real-life problems. Therapists use in-session practice to help develop skills, including identifying the problem, generating solutions, weighing pros and cons, making a decision, and evaluating an outcome. Therapists use methods such as token response cost (the child receives tokens for good behavior that can then be cashed in for a prize), corrective feedback, and social reinforcement to develop problem-solving skills gradually. Treatment consists of approximately 25 sessions lasting 40 to 50 minutes, conducted with the child and with occasional parent contact.
- *PSST and PMT*—In this combined format, the 2 types of trainings already described separately are provided individually to children and parents rather than in a group format, and the child and parent components occur concurrently. The content of the 2 approaches is not overlapping, but parents and children are each informed of what the other is learning.
- *Collaborative problem solving (CPS)* is a cognitive behavioral model that posits that chronic and severe externalizing behavior is the product of incompatibility between a child's skills set and the demands placed on him or her by the environment. CPS suggests that lagging cognitive skills interfere with a child's ability to comply with adult expectations. Contrary to conventional approaches that suggest children use their difficult behavior willfully to get or avoid things and prescribe corresponding interventions that focus on increasing motivation, the philosophy of CPS is that challenging children lack the thinking skills required to behave adaptively. Analogous to the contemporary view of children with learning disabilities who are performing below their potential in academic areas, CPS asserts that children who are not successful in complying with behavioral demands have skill deficits in critical areas such as flexibility, social perception, attention and working memory, language processing, or emotion regulation. Thus, in contrast to behavioral approaches, the corresponding intervention focuses on improving these skills rather than increasing the motivation to comply. The Thinking Skills Inventory is used to identify specific skill deficits along with the situations in which these lagging skills cause difficulty meeting adult expectations. A simple framework of 3 options (referred to as plan A, plan B, and plan C) is provided for adults to decide how best to respond to chronic problems and unmet expectations. Interventions are then tailored to assist the child in developing the skills that are lagging. The skill-building process occurs in the context of problem

Continued

solving in a natural setting. CPS is a family therapy designed for ages 4 to 18 years. Primary benefits of the model include a reduction in observed oppositional and defiant behaviors as well as a decrease in related disciplinary and restrictive interventions, including restraints and seclusion. Secondary benefits of

the model have included reduction in adult stress, improvements in adult-child relationships, and decreased staff and patient injuries. Significant reductions in oppositional behaviors have been documented in published research in both family therapy and multifamily groups.

**Table 302-1****Effective Treatments for Children With Oppositional Defiant Disorder Mentioned Frequently in the Literature**

INTERVENTION	DESCRIPTION	EXAMPLE
Collaborative problem solving (CPS)	A child's challenging behavior is because of poor flexibility, frustration tolerance, and problem-solving skills. These skills are modeled and taught through a structured process of resolving problems collaboratively with children.	Child chronically refuses to begin homework. Rather than threaten punishment, the parent enlists the child in a proactive conversation aimed at clarifying both adult and child concerns and then together brainstorming potential solutions that are mutually satisfactory.
Parent-child interaction therapy (PCIT)	PCIT uses 2 phases of training: child-directed interaction in which parents are trained in nondirective play skills to alter the quality of parent-child interactions, and parent-directed interactions that focus on improving parenting skills by teaching parents to give clear instructions, praise for compliance, and administer time-out for noncompliance.	Parent sets aside 20 minutes every day to build Legos with child. When child picks up clothes and puts in the laundry, parent is verbally praising. When child refuses to pick up clothes, parent administers time-out.
Parent management training (PMT)	Parents are usually taught how to define, observe, and record behavior at the beginning of treatment because after behaviors (eg, fighting, tantrums) are defined concretely, reinforcement and punishment techniques can be applied. Reinforcement for prosocial and nondeviant behavior is central to treatment.	Child refuses to begin homework. Parent establishes a sticker chart that gives daily points for doing homework, and at the end of the week a prize is earned if the child accrues enough points. If child does homework without being asked, child receives double points and verbal praise.
Multisystemic therapy (MST)	MST interventions typically aim to develop youth competence by improving the relationships, interactions, and skills of those who surround the youth, especially family members. Services are delivered in the natural environment (eg, home, school, community), with the treatment plan being designed in collaboration with family members, and are therefore family driven rather than therapist driven.	Child refuses to obey his nightly curfew. Parent speaks with parents of neighborhood peers and local YMCA director and has a group meeting with child and these community members to discuss the importance of the curfew.

### Emergency Situations

In general, a diagnosis of ODD does not necessitate admission to a medical or psychiatric hospital. Indications for admission include the following:

- Symptoms from any psychiatric conditions related to ODD such as anxiety or depression that make a child unsafe—wishing harm to either self or others
- An adverse reaction or result from a trial of medication
- An accidental injury (resulting from severe dysregulation caused by the child's ODD symptoms) such as losing control and becoming so upset the child falls or harms himself or herself in some way

In severe cases that reflect these criteria, a hospitalization may be helpful in providing diagnostic clarification and, in the case of significant comorbidity, may help optimize the psychopharmacologic regimen in a setting where changes can be closely monitored. Acute changes in mental status as well as new onset of severe aggression should prompt an urgent evaluation and consideration of an admission for both medical and psychiatric assessment.

With complex comorbidities, especially ADHD, anxiety, or mood disorder, a child or teen may need not simply a weekly therapy (discussed earlier) but a more intense treatment such as a day program, residential facility, or inpatient admission. ODD along with depressed mood or suicidal ideation presents an increased risk for self-injury and suicide. Family history of aggression, parenting style, any exposure to drugs or alcohol, imminence of harm to self or others, and the family's ability to contain the child's behavior are included in the risk assessment. Lastly, given the complex nature of the presentation, the pediatrician in conjunction with the mental health physician needs to consider whether aggression is a reaction to an abusive situation, which would prompt a referral to child protective services.

The AAP suggests involving a mental health specialist immediately if indicated by the following circumstances:

- Child is younger than 5 years
- Child's problems do not respond to primary care intervention
- Family is struggling to maintain a calm, consistent, or safe environment—explosions are so severe that safety is a major concern
- Child's behaviors are injurious to other children, themselves, or animals
- Child has comorbid depression
- Child has comorbid anxiety (the combination of shyness, anxiety, and behavior problems is thought to be risky for future behavior problems)
- School problems are interfering with academic success and friendships
- Child or teen is involved with legal authorities

### Role of the School

As outlined in the Evaluation section, receiving teachers' input is crucial in determining a diagnosis and a treatment plan. The mental health physician and the pediatrician must determine which person will be in regular contact with the school. Often this is the mental health physician's role, but the pediatrician as a comanager of the care must be aware of the dynamics

at school as well. A key concern is that problems with schoolwork such as refusal to take tests, forgetting to hand in homework, misplacing books, not participating in class, and being unable to settle down to work may be inappropriately attributed to laziness or lack of motivation by school staff when in fact they may be a result of deficits in crucial thinking skills (see Box 302-5) often related to ODD. Children under law have the right to receive counseling support if their emotional and behavioral challenges are affecting their academic success (see Tools for Practice).

However, unlike academic learning disabilities, it can be difficult for educators to see behavioral challenges as a form of developmental delay or "learning disability." Education of the child, parents, and school staff regarding the inadvertent labeling of oppositionality as willful, manipulative, and intentional is crucial. If adults perceive oppositional behavior as intentional, then the aim of intervention at school will be to use motivational procedures to foster compliance. If school staff perceives the child's oppositionality as the result of lagging skills, the interventions will focus on skill building instead. In addition, not infrequently a child with ODD also has a learning disability and may display challenging and distracting behavior in relation to his or her learning struggles; thus, identifying any learning challenges is essential. If warranted, a child may receive an Individualized Education Plan (IEP) as stipulated by law. If behavior interferes with an individual child's academic performance or the ability of other children in the classroom to learn, then a Functional Behavior Analysis (FBA) and a Behavior Intervention Plan (BIP) are necessary to delineate what behaviors a youth displays, factors that escalate the behavior, and appropriate interventions. Consideration of the best placement of a child (eg, mainstream classroom with or without assistance from an aide, special education setting, private placement) and accommodations can be accessed through an IEP or 504 plan. A 504 plan is a plan developed to make certain that a child who has a disability identified under the law, and who is attending an elementary or secondary school, receives accommodations that will ensure his or her academic success. Sample letters requesting a 504 plan or IEP, as well as additional information on these programs, are available in *Addressing Mental Health Concerns in Primary Care: A Clinician's Toolkit*, a CD-ROM by the American Academy of Pediatrics (see Tools for Practice).

There is no doubt that students who are defiant or noncompliant can be among the most challenging to teach. They can frequently interrupt instruction, often do poorly academically, and may seem to have little motivation to learn. A compilation of research offers many specific ideas for helping oppositional students in the classroom (see Tools for Practice).

### CASE REPORT RESOLUTION

In the presentation of Keenan at the start of the chapter, his mother stated, "Nothing is ever easy with him." This description of life at home, combined with teacher report of Keenan's struggle to keep friends and comply with requests, is a red flag that a behavior disorder such as ODD be considered. On completing a detailed history

**BOX 302-5 Thinking Skills Inventory****LANGUAGE AND COMMUNICATION SKILLS**

- Understands spoken directions
- Understands and follows conversations
- Expresses concerns, needs, or thoughts in words
- Is able to tell someone what's bothering him or her

**ATTENTION AND WORKING MEMORY SKILLS**

- Stays with tasks requiring sustained attention
- Does things in a logical sequence or set order
- Keeps track of time; correctly assesses how much time a task will take
- Reflects on multiple thoughts or ideas at the same time
- Maintains focus during activities
- Ignores irrelevant noises, people, or other stimuli; tunes things out when necessary
- Considers a range of solutions to a problem

**EMOTION- AND SELF-REGULATION SKILLS**

- Thinks rationally, even when frustrated
- Manages irritability in an age-appropriate way
- Manages anxiety in an age-appropriate way
- Manages disappointment in an age-appropriate way
- Thinks before responding; considers the likely outcomes or consequences of his/her actions
- Can adjust his/her arousal level to meet the demands of a situation (e.g., calming after recess or after getting upset, falling asleep/waking up, staying seated during class or meals, etc.)

**COGNITIVE FLEXIBILITY SKILLS**

- Handles transitions, shifts easily from one task to another

- Is able to see "shades of gray" rather than thinking only in "black-and-white"
- Thinks hypothetically, is able to envision different possibilities
- Handles deviations from rules, routines, and original plans
- Handles unpredictability, ambiguity, uncertainty, and novelty
- Can shift away from an original idea, solution, or plan
- Takes into account situational factors that may mean a change in plans (Example: "If it rains, we may need to cancel.")
- Interprets information accurately/avoids over-generalizing or personalizing (Example: Avoids saying "Everyone's out to get me," "Nobody likes me," "You always blame me," "It's not fair," "I'm stupid," or "Things will never work out for me.")

**SOCIAL THINKING SKILLS**

- Pays attention to verbal and nonverbal social cues
- Accurately interprets nonverbal social cues (like facial expressions and tone of voice)
- Starts conversations with peers, enters groups of peers appropriately
- Seeks attention in appropriate ways
- Understands how his or her behavior affects other people
- Understands how he or she is coming across or being perceived by others
- Empathizes with others, appreciates others' perspectives or points of view

and physical examination of Keenan, you are increasingly convinced that the willful, noncompliant, hostile behavior described by his mother, and now encroaching on his school day, meets criteria for ODD. You are aware, given the high comorbidity of ODD and depression, that his irritability, grouchiness, and comments such as, "You think I am a bad kid" may be symptoms of a depressive disorder. At this point you decide to have the parents and teachers fill out the SNAP-IV rating scale (see Tools for Practice). These measures are available to the public, are useful and supportive documentation of diagnostic criteria, and can be instructive in exploring the possibility of comorbid ADHD, depression, or anxiety. In a brief letter requesting that the teacher fill out the SNAP-IV scale, you also ask for any additional school information, such as grades, written evaluations, or achievement testing results. You also suggest that Keenan's mother write a letter to the school asking for an evaluation of Keenan to rule out any learning disabilities. You elect not to do any imaging or laboratory tests given that Keenan's history and physical examination are not suggestive of a diagnosis that requires that type of information. However, you do make an otolaryngologist referral to rule out OSA because Keenan's mother reports he "wakes frequently

during the night" and you know that poor sleep can be a factor in disruptive behavior. You presume the otolaryngologist will order a radiograph to get a better look at his adenoids.

On the follow-up visit, you have reviewed the teacher and parent results of the SNAP-IV as well as the information the school has sent you about Keenan. You note that on the SNAP-IV Keenan meets criteria for ODD. From his presentation of sullenness and irritability (a subtype of ODD referred to as "dysphoric" or "irritable"), you still cannot rule out a form of depression, but the school narratives and feedback from Keenan's mother indicate this demeanor may be more in relation to Keenan's awareness of how annoyed both his teachers and parents feel with his behavior rather than a biologic depression. Keenan seems relatively happy outside the context of frustrating situations. However, Keenan may have begun to internalize the sense that "I am a bad kid," so you consider referral to a mental health physician to better understand if Keenan meets criteria for depression independently or whether his moodiness is secondary to the frequent conflicts at home and school.

You confirm with his mother and stepfather that Keenan does meet criteria for ODD and review the cause and possible treatment options. In collaboration

with his parents, you design a treatment plan for Keenan. You share your concern about Keenan's mood and advise that you would like to better understand whether it is a chronic state or mostly related to moments of frustration. The mother confirms that testing has been requested at school to rule out learning issues. You mention that depending on those results a neuropsychological battery might be of help as well. The plan includes a referral to a child psychologist to rule out depression and a referral to an individual physician or a local mental health clinic that offers one of the evidence-based treatments for ODD. With the permission of Keenan's mother and stepfather, you draft a follow-up letter to the school explaining the diagnosis and the need for ongoing communication and willingness to try new ways of working with Keenan in school.

After you have referred Keenan to the mental health physician or nonphysician clinician, you clarify your role in comanaging the case. In the next few visits with Keenan you discuss his progress. The psychologist treating Keenan readministers the SNAP-IV to his parents and his teacher and finds that Keenan's hostile, negative behavior has decreased slightly. His mother reports that since trying to reduce areas of conflict, be less rigid about expectations, focus less on being punitive for bad behavior, and offer lots of positive feedback for what Keenan does well, there has been less tension at home (see the discussion of CPS in Box 302-4). Keenan reports feeling that he doesn't think his mother, stepfather, and teachers are "out to get him" anymore but that he still "gets really mad." The psychologist has shared with you that she agrees it is premature to assign a label of depression because much of Keenan's grumpy mood seems connected to his frequent level of conflict with others. The psychoeducational testing reveals moderate dysgraphia, and although he has solid comprehension, reading fluency is quite slow. These 2 findings help to explain why Keenan becomes disruptive and oppositional when asked to do writing or reading assignments—he doesn't have the skill to do them and doesn't know how to understand or communicate this struggle. All Keenan knows is that he hates to read and write. The psychologist has already suggested his parents explore an IEP to get support for both of these areas, and you reiterate the helpfulness of pursuing an IEP. You also review the report from the otolaryngologist who says that although they are enlarged, she does not think Keenan's adenoid or tonsils need to be removed; however, he probably has chronic colds, making breathing hard when he sleeps. A nasal spray is prescribed.

After 4 months following a treatment program, Keenan and his mother should report less conflict at home. His teacher should also feel she better understands why Keenan can be challenging and has new ways to work with him to teach him skills as he navigates his school day. Your role is to continue to comanage Keenan's care with the mental health specialist and to help Keenan and his mother identify Keenan's strengths as well as the challenging situations that need to be resolved so that Keenan has the best support to succeed.

## CONCLUSIONS

Oppositional defiant disorder is a common disorder of childhood and adolescence affecting functioning across multiple areas of a child or teen's life. If left untreated, the symptoms of ODD are likely to become more severe and associated with comorbid depression or anxiety or develop into CD. Diagnosis and treatment are complicated in that there is no clear test or biologic marker, there are high rates of comorbid conditions, and there is a need to coordinate care across multiple settings. There is no one-size-fits-all approach to the treatment of ODD. The treatment for a child whose oppositional behavior is fueled by attention and working memory deficits (see Box 302-5) should differ in meaningful ways from the treatment of a child whose oppositional behavior is fuelled by perfection and obsessiveness and should differ in still other ways for a child for whom language processing is a struggle. Children and teens with ODD can function well at home and at school provided their behavior is recognized not as willful and intentional but as a result of lagging skills. Parents, teachers, and physicians have noted that children whose symptoms are recognized, assessed, understood, and treated at an earlier age will show improved sense of themselves as positive members of their school or family and experience more success. The primary care physician's role is to assure the child and parent that this is not a lifelong disorder and that there are good, helpful interventions that do have excellent outcomes.

## ONGOING CARE

### Follow-up

Oppositional defiant disorder, regardless of the presence of CD, is a highly comorbid condition with the potential for negative outcomes in children and adolescents. Continuing to make sure parents and teachers are working to develop a child's skills rather than becoming more punitive to manage challenging behavior is an ongoing effort.

### Prognosis

There is emerging evidence that psychiatric diagnoses can be reliably ascertained in preschool populations. Approximately half of all children who meet criteria for ODD as preschoolers will have no psychiatric problems by age 8 years. CD symptoms are the most robust predictor of severe and persistent forms of antisocial behavior, but ODD symptoms also predict persistent involvement in the juvenile justice system even when controlling for the co-occurring CD symptoms. ODD and ADHD symptoms independently predicted increases in conduct problems over time as well as the development of internalizing and social problems. Children who meet criteria for ODD are about 4 times more likely to meet criteria for a personality disorder when they grow up than those who do not carry this diagnosis, approximately a 15% chance. By the time preschoolers diagnosed with ODD are 8 years old, only 5% still meet criteria for ODD and nothing else. About 5% to 10% of preschoolers with ODD will eventually meet criteria for ADHD with no signs of ODD. By the time children diagnosed with ODD are at

the end of elementary school, about 25% will have mood or anxiety problems that are disabling. Later in life, ODD can develop into CD, which in turn may develop into passive-aggressive personality disorder or antisocial personality disorder. As is the trend with so many psychiatric disorders, the earlier ODD is diagnosed and the pediatrician helps develop an accurate understanding in the parents of the child's challenges, the more likely the child is to progress developmentally to the point of no longer meeting criteria for ODD.

### Prevention

The best prevention is to urge parents to set developmentally appropriate and realistic expectations with their preschoolers and work to help build their problem-solving, flexibility, and frustration tolerance skills. Accurate and compassionate understanding of developmental problems in these areas can prevent cycles of punitive responses to challenging behavior.

## Chapter 303 OSTEOCHONDROSES

Donna M. Pacicca, MD

Osteochondroses (categorized by anatomic location in Table 303-1) result from a disturbance of endochondral ossification of growing bones, which may lead to altered growth in the epiphysis or physis. Varying degrees of discomfort, dysfunction, and deformity may occur with osteochondroses. Ossification centers of growing bones often develop irregular mineralization during childhood that is self-limited and often found incidentally on radiographs. The osteochondroses are characterized by symptoms, such as pain and limping, progressive change in the epiphysis, and persistent deformity after resolution.

Apophysitides are also caused by a disturbance of endochondral ossification, but generally are limited to the apophyses and do not cause any potential abnormalities to joint surfaces.

The literature initially describing these entities is old—many of these disorders were described shortly

after radiographs came into clinical use (Box 303-1, 303-2).

### FEMORAL HEAD

Legg-Calve-Perthes refers to a disorder characterized by idiopathic osteonecrosis of the femoral head. The cause is unknown, but it is suspected that the disorder is caused by vascular insult to the femoral head ossification center. Age of onset is generally in early school-age years (4–12), occurring in boys 4 times more frequently than in girls. Most cases are unilateral; in the 10% to 15% of patients with bilateral disease, the hips are usually involved successively.

Children generally present with an intermittent limp, especially after activity. The limp is often associated with hip, thigh, or knee pain. Children may develop loss of internal rotation and abduction because of pain and subsequent deformity. The diagnosis is made on the basis of plain radiographs, which initially may show only height difference, but later show lucency or collapse of the femoral ossific nucleus (Figure 303-1, Figure 303-2). The acute phase of the disease lasts several weeks, with the remodeling phase lasting months to years. In addition to the deformity caused by the collapse of the ossific nucleus, there can be further deformity as a result of abnormal growth of the proximal femoral physis, which may be involved in the disorder as well.

### PROXIMAL TIBIA

Physiologic bowing is common in infants and often persists until 18 months, after which the legs straighten and then progress to a slight degree of knock-knee. Bowing of the legs that persists or progresses beyond 2 years should be evaluated.

**Table 303-1** Osteochondroses

SITE	PEAK AGE AT APPEARANCE (YEARS)
<b>UPPER EXTREMITY</b>	
Humeral head	2–8
Humeral capitulum	4–10
Lower ulna	13–20
Carpal navicular	16–24
Carpal semilunar	16–20
Bilateral entire carpus	10–14
Metacarpal heads	9–15
Basal phalanges	8–14
<b>LOWER EXTREMITY</b>	
Femoral epiphysis	3–12 <sup>a</sup>
Greater trochanter	6–11
Primary patellar center	8–15
Secondary patellar center	8–10
Shaft of tibia	1–5 <sup>b</sup>
	6–12 <sup>c</sup>
Tibial tubercle	10–15
Distal tibial epiphysis	4
Calcaneal epiphysis	3–18
Astragalus	2–8
Tarsal navicular	3–7
Second metatarsal	8–17
Fifth metatarsal	8–16
<b>SPINE AND PELVIS</b>	
Vertebral epiphysis	13–20
Vertebral disk	> 16
Symphysis pubis	12–18
Iliac crest	12–19
Ischial apophysis	13–18
Ischiopubic synchondrosis	12–19

<sup>a</sup> Maximum is 6–8 years.

<sup>b</sup> Form of disease in infants.

<sup>c</sup> Form of disease in adolescents.

### BOX 303-1 Clinically Significant Sites of Osteochondroses

#### LOWER EXTREMITY

- Femoral head (Legg-Calve-Perthes disease)
- Proximal tibial physis (infantile and juvenile Blount disease)
- Tarsal navicular (Köhler disease)
- Metatarsal heads 2, 3, or 4 (Freiberg infraction)

#### UPPER EXTREMITY

- Capitellum (Panner disease)
- Lunate (Kienbock disease)
- Scaphoid

### BOX 303-2 Common Apophysitides

- Tibial tuberosity (Osgood-Schlatter disease)
- Distal pole patella (Sinding-Larsen-Johannson syndrome)
- Calcaneal apophysis (Sever disease)

In Blount disease, normal growth is slowed at the posteromedial proximal tibial physis, resulting in a complex deformity that causes clinical bowing and internal torsion (Figure 303-3). The cause is unknown, but histologic evaluation has shown disruption of the normal architecture of the growth plate, with replacement by fibrous tissue and even bone in very severe cases. The condition was first described by Walter Blount in 1937, and the etiology is still unknown. While there is association with obesity, early walking, and race (Latino or African-American), these are only predisposing factors. Most children with Blount disease that persists or develops beyond age 4 require an osteotomy to correct the bowing. However, earlier treatment often focuses on guided growth to allow for gradual correction of the deformity via a plate or similar device to slow growth on the lateral side of the tibia.

**Figure 303-1** Early presentation of Perthes disease. Note difference in height of epiphysis.

Differential diagnosis includes persistent physiologic varus, vitamin D–deficiency rickets, renal osteodystrophy, vitamin D–resistant (hypophosphatemic) rickets, metaphyseal dysostosis (Schmid, Jansen types), spondyloepiphyseal or metaphyseal epiphyseal dysplasias, thrombocytopenia-absent radius syndrome, focal fibrocartilaginous defect, or proximal tibial physeal injury (eg, infection, fracture, irradiation). There is an adolescent form of Blount’s disease that may present initially with knee pain and progressive varus deformity (Figure 303-4). As with the juvenile form, cause is unknown, but is suspected to be a combination of obesity and possible persistent physiologic varus. Radiographs may demonstrate widening of the medial physis in addition to varus and flexion deformities of the proximal tibia. Treatment is surgical.

### TARSAL NAVICULAR

Köhler disease of the tarsal navicular bone results from an interruption of the blood supply to the developing navicular bone, causing necrosis of its ossification center. The disorder is seen primarily in boys between 2 and 9 years of age.

The child often ambulates in equinovarus and complains initially of pain with activity. Palpation of the bone elicits tenderness. Radiographs of the feet show irregularity of the navicular ossification center with collapse, sclerosis, or fragmentation (Figure 303-5). However, these radiographic findings can be seen in asymptomatic children and may represent a normal variant of ossification. The clinical findings are key to making the diagnosis.

The process of revascularization and reconstruction takes from months to years. Initial treatment is symptomatic; use of a cast or walking boot may alleviate pain, and physical therapy may be helpful in the older, more active child. The condition is self-limited, and the ossification center eventually becomes revascularized and completely reconstructed.

**Figure 303-2** (A) Initial presentation of Perthes in a 7-year-old. Note lucencies in femoral head. (B) After surgical intervention and healing of disease, there is still asymmetry in the femoral head.

**Figure 303-3** Juvenile Blount disease. (A) Unilateral. (B) Bilateral.

**Figure 303-4** Adolescent Blount disease. (A) Clinical photo. (B) Radiograph.

## METATARSAL HEADS

Freiberg infraction, first described in 1917, is a condition in which a part of the head of a metatarsal bone undergoes osteonecrosis and becomes sufficiently weakened to be susceptible to functional trauma (running, jumping), which may cause compression-related collapse of the metatarsal head. The second metatarsal is most often involved, because it is usually the longest metatarsal; the third metatarsal bone is the next most likely. Girls are affected more often than boys, and onset usually occurs during the adolescent growth spurt.

Affected children generally have pain with ambulation that localizes to the metatarsal head. This is

**Figure 303-5** Typical sclerotic collapsed appearance of tarsal navicular in Köhler disease.

reproducible with palpation. Occasional swelling because of joint effusion may be seen. Children will also complain of painful range of motion of the metatarsophalangeal joint.

Radiographs show sclerosis early in the course of the disease, with collapse and possible arthritic changes occurring later (Figure 303-6).

Initial treatment is with activity modification and protected weight-bearing, as well as orthotics or shoe modifications that can help to off-load the affected metatarsal and limit joint motion. Most children will improve, but for those with persistent symptoms, surgery may be helpful.

## CAPITELLUM

Panner disease is osteonecrosis of the capitellum. It is seen almost exclusively in boys younger than 10 years of age. There is no association with trauma, but children present with pain and limitation of elbow motion.

Radiographs show fissuring, fragmentation, and lucency involving the entire capitellum (lateral condyle) ossification center. Gradual reossification occurs over months to years.

Treatment is focused on rest with limited casting, and gradual resumption of activity over time.

It is important to distinguish Panner disease from osteochondritis dissecans of the capitellum, which is often associated with trauma or overuse, and has a more focal appearance on radiographs (Figure 303-7).

**Figure 303-6** (A) Initial presentation with lucency. (B) After consolidation, with flattening and deformity of head. (C) After debridement and corrective osteotomy.

### CARPAL LUNATE

Aseptic necrosis of the lunate bone (Kienbock disease or the newer term, lunatomalacia) is a rare disorder in children. Two forms are described: infantile (up to age 12) and juvenile (13 and up). Cause is unknown. Children note wrist pain, which may be accompanied by swelling. Pain is noted with wrist motion, and in longstanding cases the pain may be present at rest.

Radiographs will show a flattened sclerotic lunate. In the infantile form, the entire lunate is generally involved. In the juvenile form, there may be an elongated palmar horn.

Treatment usually begins with a period of immobilization. Surgery may be indicated in recalcitrant cases or in older children, but there is controversy over the ideal procedure.

**Figure 303-7** (A) Radiographic appearance of Panner disease with total involvement of capitellum. (B) Compared to osteochondral lesion of the capitellum, which is focal.

**Figure 303-8** (A) Typical prominent tibial tubercle of a patient with Osgood-Schlatter disease. This is the area of maximal tenderness. (B) Radiographs that may demonstrate irregular ossification of the tibial tubercle.

## APOPHYSITIDES

Apophysitides are common conditions in late childhood and adolescence that are associated with periods of rapid growth. These are clinical entities, although occasionally there may be associated radiographic changes.

Osgood-Schlatter disease is a clinical disorder that results from an inflammation/stress reaction occurring at the patellar ligament insertion into the epiphysis of the tibial tubercle. Its incidence is higher in boys than in girls, and it generally occurs in ages 10 to 14 years. More than 25% of cases have bilateral involvement. The child complains of pain and tenderness of the tuberosity, which may also be enlarged (Figure 303-8). The radiographic changes vary from no abnormality to irregular ossification of the tibial tubercle; more mature patients may demonstrate a persistent ossicle (Figure 303-8). Radiographs may not relate to the clinical presentation but can rule out other conditions like osteochondritis dissecans. Symptoms commonly include pain during or at the end of activity, and are generally alleviated by rest, ice, and nonsteroidal anti-inflammatory drugs. On examination, children will often have tight quadriceps and weak hamstrings, which may be addressed with physiotherapy. Activity restriction is often helpful initially if children are very symptomatic, followed by physiotherapy and gradual resumption of activity. Osgood-Schlatter disease is generally a self-limited condition. Surgery is rarely indicated, and is generally for a painful ossicle that is refractory to nonoperative intervention.

Sinding-Larsen-Johannson syndrome presents similarly to Osgood-Schlatter disease, but the patient localizes tenderness to the distal pole of the patella.

**Figure 303-9** Area of tenderness localizing to calcaneal apophysis in Sever disease.

Radiographs may show elongation of the distal pole patella, with occasional fragmentation. Again, this is a self-limited condition, but symptoms may resolve more quickly with physiotherapy. Surgical treatment is extremely rare. Neither condition has been shown to predispose children to fracture in these areas.

Sever disease is apophysitis of the calcaneal tuberosity, and commonly affects active children ages 9 to 12 years. While children often complain of pain in the arch or heel, they are not tender over the plantar fascia, but tender at the calcaneal apophysis and Achilles insertion (Figure 303-9). Many of these patients have tight Achilles tendons and respond to a course of physiotherapy and modified activity. While some advocate shoe modifications, inserts, or heel cups, these have not been shown to reliably and completely alleviate symptoms.

## Chapter 304 OSTEOMYELITIS

Stephanie Yee-Guardino, DO; Johanna Goldfarb, MD

Osteomyelitis, or infection of the bone, in children is most often the result of hematogenous spread of bacteria to bone. Osteomyelitis can also occur after an open fracture or operative procedure or by direct extension from an adjacent soft-tissue infection. Chronic osteomyelitis can occur if the infection is indolent and the diagnosis is delayed or if treatment does not completely eradicate infection. Acute osteomyelitis should be diagnosed and aggressively treated to decrease the risk of osteomyelitis becoming chronic; chronic infection requires surgical drainage and is more difficult to eradicate than acute cases.

Chronic osteomyelitis can result in lifelong disability related to recurrences and, rarely, to cancer. Regardless of age, osteomyelitis is most often caused by infection with *Staphylococcus aureus*; however, osteomyelitis can be caused by other pathogens in certain age groups or hosts, or the infecting agent can be related to the type of contamination (dirt, water, and other sources). Establishing the diagnosis of osteomyelitis can be difficult, especially when the illness begins insidiously. Physicians who care for children must have a high index of suspicion to avoid missing or delaying the diagnosis.

## DEFINITION OF TERMS

### Acute Osteomyelitis

In children, osteomyelitis caused by hematogenous seeding usually begins in the metaphyses of the long bones, reflecting the rich blood supply in this area throughout childhood. Often, but not always, a history of trauma to the area can be found. Occult transient bacteremia likely seeds a traumatized area more easily than a healthier site.

In infants, osteomyelitis is often accompanied by rapid spread into the adjacent joint, especially the hip. Infection seems to spread quickly across the metaphysis into the epiphysis and then into the adjacent joint. The presence of penetrating vessels that pass through the growth plate to connect the metaphysis with the epiphysis is thought to allow the rapid spread. These vessels are only present in infancy, most commonly before 6 months of age. Infection may also cross the growth plate directly (see Table 334-1 in Chapter 334, Sports Musculoskeletal Injuries, for the components of the growth plate). Infants with signs and symptoms of septic arthritis of the hip must always be evaluated for an accompanying osteomyelitis of the femur. In children older than 1 year of age, infection tends to be held in place by the metaphysis. Infection after infancy is most likely to spread into the diaphysis and down the bone. However, infection of the hip, shoulder, or elbow joints can also be the result of infection breaking out of the cortex located within the joint capsule. Much more rare is infection that begins in the epiphyseal or metaepiphyseal area. *S aureus* is the organism most likely to be responsible for hematogenous osteomyelitis in all age groups. In newborns, other common pathogens include group B streptococcus (*Streptococcus agalactiae*) and gram-negative bacteria such as *Escherichia coli*. Fungal pathogens, especially *Candida* species, occur in infants who have been in the neonatal intensive care unit and who have had vascular lines in place. In older infants and children, *S aureus* followed by the group A *Streptococcus* (*S pyogenes*) are the most common pathogens. Because an effective vaccine has been developed, *Haemophilus influenzae* type b infection has become very rare, but was previously a common pathogen in preschool-age children. *S pneumoniae* occurs mostly in children younger than 2 years, and *Kingella kingae* occurs in young children. Children with hemoglobinopathies are at risk for osteomyelitis, perhaps related to bone infarcts that occur with sickle cell crisis. In this population, *Salmonella* species and *S aureus* are the most

common pathogens. *Salmonella* infections in this population occur at rates much higher than in other children, who only rarely have this pathogen as a cause of osteomyelitis. Organisms that cause a bacteremia can result in an osteomyelitis in the child.

Osteomyelitis following direct invasion of the joint is also most often caused by *S aureus*, but other pathogens and sometimes multiple pathogens can be present. In osteomyelitis, the nearby joint can also be affected with a reactive effusion. In children, trauma is most often the cause, especially after an open fracture, but this circumstance can also occur after orthopedic surgery, especially in the setting of placement of a foreign body such as the insertion of pins or screws into bone. In addition to *S aureus*, coagulase-negative staphylococci, gram-negative organisms, and other unusual organisms can become pathogens. Unusual pathogens reflect the source of contamination. For instance, *Pseudomonas aeruginosa* commonly follows puncture wounds of the foot through a sneaker; *Aeromonas* infections may occur after trauma to bare feet while walking in river water. Multiple pathogens, including anaerobes, may be present, especially if the wound has been contaminated with dirt.

### Chronic Osteomyelitis

Chronic osteomyelitis refers to infection in the bone that has become long-standing (usually months of untreated infection), often related to a delay in the diagnosis or to incomplete eradication of an acute infection. Chronic infection is most often indolent and much harder to cure than acute osteomyelitis. Infection can spread insidiously throughout the diaphysis of the affected bone. This spread can occur even with a staphylococcal species when an infection begins around a foreign body such as a pin to stabilize a bone after orthopedic surgery. Infection in chronic osteomyelitis can track outward to result in a spontaneously draining sinus. A sinus tract that closes can result in more acute symptoms and signs. Chronic osteomyelitis results in bone loss and areas of devascularized bone, which separate and result in the creation of sequestrum or pieces of dead bone in the shaft of the long bones. Once this situation occurs, surgery will be required to treat the infection. A *Brodie abscess* is an abscess with a capsule that can develop in the bone and seems to be the result of walled-off chronic infection, often with no active organisms recoverable when drained.

## DIFFERENTIAL DIAGNOSIS

Osteomyelitis should always be considered in a child who has localized bone pain, especially if fever is present, which may be low grade. Trauma can be confused with bone infection, especially if fever is minimal. In many instances, osteomyelitis does follow a fracture or trauma; thus even in the presence of a fracture, the possibility of osteomyelitis must be considered if fever is present or pain persists after casting. Fever may be minimal and can be overlooked by both parent and physician. Careful examination, seeking focal areas of tenderness, is necessary in the young child who may not be able to describe pain adequately. Hip or femur pain can be confused with intra-abdominal infection,

especially infection in the area of the psoas muscle. An example is a missed appendicitis that can result in a phlegmon in this area, causing a limp that can be confused with osteomyelitis of the femur. Careful abdominal examination is, therefore, necessary in the child who limps, to avoid missing intra-abdominal abnormalities. Back pain and discitis can also be confused with osteomyelitis. The differential diagnosis of a child with back pain must include vertebral body infection, with or without nearby epidural abscess and discitis. Bone pain can also be a presenting symptom of leukemia. An abnormal blood count with anemia, a low white blood count, or thrombocytopenia will often be a clue. Cat-scratch disease can cause osteomyelitis and be confused with lymphoma or other malignancy, but this condition resolves untreated over time. Some bone tumors can cause nonspecific bone pain and lytic bone lesions on radiograph that must also be differentiated from chronic osteomyelitis by biopsy for pathologic abnormalities and by culture of the bone. When fever is not a prominent sign, osteomyelitis is more likely to be confused with a condition not caused by infection. The differential diagnosis of a limp also includes septic arthritis and juvenile idiopathic arthritis. The manifestations of septic arthritis may be similar to those of acute osteomyelitis, and, especially in the infant, these entities may coexist. When septic arthritis is present, the urgency for prompt treatment is acute (see Chapter 328, Septic Arthritis). When erythema over the infected bone is present, distinguishing between cellulitis and osteomyelitis may be difficult. Chronic multifocal osteomyelitis is a recurring inflammatory disease that most often is not associated with infection but can mimic bacterial osteomyelitis. In many cases, it can only be diagnosed over time by observing the pattern of recurring disease, usually with cultures negative for acute infection.

## EVALUATION

### Relevant History

Localized bone pain and fever is the history most typically given in acute osteomyelitis, at times with prior trauma to the area. In infants and young children, the caregiver may have noticed that the child has pain with movement of the affected limb, has stopped using the limb, or has begun to limp. When the infection causes bacteremia, a history of a high fever spike before the onset of pain may be described, or, if ongoing, signs of bacteremia may be present, such as chills and high fever, malaise, and acute illness. In older children, 1 bone is usually involved, whereas in newborns, more than 1 site may be infected with a bacteremia. Nonspecific malaise and poor appetite may occur in the child with chronic osteomyelitis, but only nonspecific complaints of pain may be elicited in the area of the bone. Specific pathogens may have unique histories, such as the child with gastroenteritis and *Salmonella* infection who later has new fever and bone pain, or the child with an open fracture or bone surgery who later develops fever and new pain or drainage at the same site. A child with a fracture, either open or closed, who has new or worsening pain under a cast should have the cast removed and the area evaluated for infection.

The history may be acute, especially if the child is bacteremic, or more subacute or chronic in cases in which the bacteremia has resolved or the pathogen is less virulent. In chronic osteomyelitis, symptoms may have been present for months.

### Physical Examination

Vital signs of the child with osteomyelitis may be normal, especially with chronic infection, or abnormal if the child is bacteremic at presentation. Fever will often be present, even in the absence of a history of fever. Localized pain will almost always be present. Tenderness is often exquisite, but in younger children, only a new limp or absence of movement of an arm or leg may be noted. Other local signs may be associated with inflammation, including swelling, redness, and warmth over the involved bone, which can be confused with cellulitis. Characteristically, the child is reluctant to move the adjacent joint and, when a lower extremity is involved, may refuse to bear weight. In the young infant, the loss of active movement in an extremity may be confused with a neurologic problem. Erythema is often present over the infected bone, in addition to tenderness to palpation or movement. If associated arthritis occurs, then pain on movement of the joint may be prominent.

### Laboratory Testing

The diagnostic evaluation for possible osteomyelitis includes a complete blood cell count and smear review, erythrocyte sedimentation rate, C-reactive protein, blood cultures, and radiographs. However, all of these tests can produce normal findings, especially early in the infection. The white blood cell count can be elevated in acutely ill children with bacteremia, though very low counts occur with sepsis, especially in infants. The presence of anemia, low white blood cell count, or thrombocytopenia in the absence of disseminated intravascular coagulation should raise concern for leukemia or other malignancy. The sedimentation rate may be normal at first but almost always becomes elevated in acute osteomyelitis and often is extremely elevated, differentiating osteomyelitis from other inflammatory processes except autoimmune ones. The C-reactive protein is usually elevated early. These clinical markers are helpful in following the course and response to treatment. The C-reactive protein rises more quickly and normalizes more rapidly than the sedimentation rate, which eventually is most useful in following long-term therapy. Procalcitonin has been studied as a specific marker in differentiating acute osteomyelitis and septic arthritis from viral and noninfectious inflammatory bone and joint infections and may be a useful tool in the future. A blood culture will often identify the pathogen causing the infection, but is not always positive. In chronic osteomyelitis, laboratory markers of inflammation may be normal, making the diagnosis more difficult. In some cases, a TB test by serum interferon may be appropriate, such as in the older child in whom TB is being considered as a cause of infection.

### Imaging

Early in the clinical course, no bony changes are seen radiographically; the earliest detectable signs are

those of blurred soft-tissue planes secondary to edema spreading into fatty tissues. Bone changes are not apparent until at least 7 to 10 days or longer after the onset of symptoms. The first signs consist of nonspecific periosteal reaction. Lytic lesions occur later. Bony radiographs should always be obtained, however, to exclude other pathologic abnormalities such as fracture or a malignant lesion. Although skeletal scintigraphy (technetium bone scan) was recommended in the past for evaluating children with possible osteomyelitis, the advantages of using magnetic resonance imaging (MRI) initially have become clear. MRI provides excellent views of the bony and soft-tissue anatomy, revealing subperiosteal abscesses that require surgical intervention. The use of contrast is helpful with the MRI. The presence of a subperiosteal abscess is diagnostic for an acute osteomyelitis that has broken through the metaphyseal cortex. MRI is also the image of choice when pelvic or spine osteomyelitis is suspected. Very rarely, MRI may be normal at first. Technetium bone scans are sensitive, though less sensitive than MRI, are also less specific, and are often difficult to interpret, with frequent false-negative results. Bone scans are not useful in the neonate because of low bone mineralization. Bone scans provide limited information regarding soft-tissue involvement, subperiosteal space, and bone marrow edema, and the results may be normal in up to 20% of children in the first days of illness. This can occur with MRI, but much less frequently. In addition, malignancy, cellulitis, trauma, and bone infarction can affect the specificity of a bone scan, though 3-stage scans improve sensitivity. Finally, bone scans require large amounts of radiation. However, the bone scan does not ordinarily require sedation or general anesthesia, which frequently are needed for a young child to lie still for an MRI. Bone scans can be useful in cases in which multiple sites of osteomyelitis are suspected.

Ultrasonography can detect a subperiosteal abscess and may be helpful in guiding needle aspiration of an infected bone. The finding of such a collection distinguishes osteomyelitis from cellulitis in an inflamed extremity, but the failure to visualize an abscess does not rule out early osteomyelitis still contained within the bone. Ultrasound also can help evaluate a nearby joint for an effusion that is present with an associated arthritis.

In chronic osteomyelitis, the radiograph will show extensive disease, usually along the diaphysis of the bone, with bone changes that may need to be differentiated from malignancy by history and ultimately by cultures and biopsy.

## MANAGEMENT

A blood culture and a needle aspirate of the site of infection are the most helpful procedures for diagnosing osteomyelitis. Aspiration confirms the diagnosis and can determine the necessity for operative decompaction if frank pus is obtained, may alleviate pain caused by pressure from an abscess, and provides a specimen for pathogen identification by culture and material for immediate Gram stain. Blood cultures are also helpful in identifying the presence of bacteremia

and the cause of the infection, and they are positive in 40% to 50% of cases. If the history and examination fit with the diagnosis and a blood culture is positive, then therapy can be started without a bone aspiration. If response to therapy is prompt, then aspiration may not be required. Needle aspiration of the subperiosteal space and of the metaphysis for culture is indicated to obtain culture identification of the pathogen when blood cultures are pending and whenever a collection of pus exists. When surgery is indicated, it should be prompt and antibiotics should be started as soon as culture material is obtained. In indolent cases and in cases with unusual presentations, aspirating the bone is especially important to obtain the pathogen and to guide therapy. Evaluation for related arthritis also is crucial, given that joint infections can progress rapidly and need adequate drainage to avoid damage to the joint (see Chapter 328, Septic Arthritis). If infection with TB is suggested because of history or setting, then cultures for acid-fast bacteria should be included as well as a tuberculin skin test or IGRA (interferon-gamma release assay) blood test, depending on the age of the child.

Once blood cultures and needle aspiration have been performed, antibiotics should be given empirically and by the intravenous route. After the newborn period, in a previously well child thought to have hematogenous osteomyelitis, a penicillinase-resistant penicillin or first-generation cephalosporin is sufficient, though clindamycin or vancomycin should be considered given the incidence of methicillin-resistant *S aureus* (MRSA) in community-associated infection. In the child who is severely ill or has signs of bacteremia and sepsis, vancomycin should be considered as initial therapy instead of or in addition to a  $\beta$ -lactam. In each case, therapy should be individualized to include other likely pathogens. For example, in the newborn, *S aureus* remains the most common cause, but *S agalactiae*, coagulase negative staphylococcus, gram-negative enterics, and *Candida* species are encountered in neonates in the intensive care unit. Initial therapy in the newborn should always include coverage against gram-negative enterics and might include oxacillin and gentamicin, or vancomycin and ceftazidime or cefepime, when concern for MRSA infection exists or for coagulase-negative staphylococci. Neonates who have been in a neonatal intensive care unit and who have been on antibiotics should be treated most broadly, pending culture results. Fungal coverage is usually not empiric therapy, unless a blood culture or other epidemiologic data suggest the presence of a fungal infection, such as in patients with chronic granulomatous disease. Children with sickle cell hemoglobinopathies who are at special risk for infection with *Salmonella* species in addition to *S aureus* might be treated with cefuroxime or with vancomycin and ceftriaxone or cefotaxime, pending culture results. If a pseudomonal infection is suspected, such as in the child with infection after a puncture wound of the foot, then the initial treatment should be ceftazidime or a carboxypenicillin or acylureidopenicillin combined with an aminoglycoside such as piperacillin-tazobactam and gentamicin or ceftazidime and gentamicin. Piperacillin-tazobactam will also treat *S aureus* while cultures are pending. Chronic

**Table 304-1 Treatment of Osteomyelitis**

CONDITION	THERAPY	COMMENTS
<b>NEWBORN</b>		
Empiric therapy	Nafcillin/oxacillin IV (or vancomycin if MRSA is a concern) AND cefotaxime or gentamicin IV	
Coliform bacteria (eg, <i>Escherichia coli</i> , <i>Klebsiella</i> sp, <i>Enterobacter</i> sp)	For <i>E coli</i> and <i>Klebsiella</i> : cefotaxime OR gentamicin OR ampicillin (if susceptible) For <i>Enterobacter</i> , <i>Serratia</i> , or <i>Citrobacter</i> : ADD gentamicin IV to cefotaxime OR ceftriaxone, OR use cefepime initially	Meropenem for ESBL-producing coliforms Piperacillin/tazobactam or cefepime are alternatives for susceptible bacilli
Gonococcal arthritis and tenosynovitis	Ceftriaxone IV OR cefotaxime IV for 7–10 days	Cefotaxime is preferred for infants with hyperbilirubinemia
<i>S aureus</i>	MSSA: oxacillin/nafcillin IV MRSA: vancomycin IV	Alternative for MSSA: ceftazolin Alternatives for MRSA: linezolid, clindamycin (if susceptible) Addition of rifampin is sometimes attempted if persistently positive cultures
Group B streptococcus <i>Haemophilus influenzae</i>	Ampicillin or penicillin G IV Ampicillin IV, OR cefotaxime IV	
<b>CHILDREN OLDER THAN 30 DAYS</b>		
Infants and children, acute infection (usually <i>S aureus</i> , including MRSA; group A streptococcus; <i>K kingae</i> )	Cefazolin +/- clindamycin or vancomycin depending on how sick the child is at presentation for serious infections For MRSA: clindamycin 30–40 mg/kg/day IV div q8 or vancomycin 60 mg/kg/day IV div Q8, maintaining troughs between 10–15 micrograms/milliliter For MSSA: oxacillin/nafcillin 200 mg/kg/day IV div q6h OR cefazolin 100 mg/kg/day IV div q8h For <i>Kingella</i> : cefazolin 100 mg/kg/day IV div q8h OR ampicillin 150 mg/kg/day IV div q6h, OR ceftriaxone 100 mg/kg/day IV Total therapy (IV plus PO) usually 4–6 wk for MSSA (with end-of-therapy normal ESR, radiograph to document healing) but may be as short as 3 wk for mild infection; may need longer than 4–6 wk for MRSA Follow closely for clinical response to empiric therapy	In children with open fractures secondary to trauma, add ceftazidime for extended aerobic gram-negative bacilli activity <i>Kingella</i> is often resistant to clindamycin and vancomycin For MSSA and <i>Kingella</i> , step-down oral therapy with cephalexin 100 mg/kg/day PO div tid Oral step-down therapy alternatives for MRSA include clindamycin and linezolid with insufficient data to recommend trimethoprim/sulfamethoxazole
Chronic (staphylococcal)	For MSSA: cephalexin 100 mg/kg/day PO div tid OR dicloxacillin caps 75–100 mg/kg/day PO div qid for 3–6 mo or longer For MRSA: clindamycin or linezolid	Surgery to debride sequestrum is usually required for cure For prosthetic joint infection caused by staphylococci, add rifampin Watch for $\beta$ -lactam-associated neutropenia with high-dose, long-term therapy, and linezolid-associated neutropenia/thrombocytopenia with long-term (>2 wk) therapy

div, divided; ESBL, extended spectrum  $\beta$ -lactamase; ESR, erythrocyte sedimentation rate; h, hour; IV, intravenous; MRSA, methicillin-resistant *Staphylococcus aureus*; MSSA, methicillin-sensitive *Staphylococcus aureus*; PO, by mouth; q, every; qid, 4 times per day; tid, 3 times per day; wk, week.

osteomyelitis must be completely drained and debrided and will require surgical care.

If infection is the result of open wounds, then the setting should guide empiric therapy. Wounds contaminated by dirt require broad coverage of gram negatives and anaerobes, such as piperacillin-tazobactam with an aminoglycoside.

Antibiotics should be adjusted once cultures and sensitivities are available, narrowing the spectrum to cover the pathogen. Clindamycin has good bone penetration and is often used in cases of allergy to  $\beta$ -lactams or to treat MRSA isolates that are sensitive. It has been recommended as empiric therapy if MRSA is suggested, though some isolates may be resistant. The role of the antibiotic linezolid in treating osteomyelitis in children remains to be determined. It should not be used empirically but may be helpful in patients with  $\beta$ -lactam allergies and as a drug that can be used orally to treat a serious infection, though the side effect of thrombocytopenia limits its long-term use. Antibiotics should be continued for 4 to 8 weeks in order to prevent complications, specifically the evolution of infection into chronic osteomyelitis. Clinical response and bloodwork will ultimately guide length of therapy. For specific treatment advice see Table 304-1.

Oral antibiotics can be considered to finish the course of therapy if an oral agent is available that has good bone penetration, has excellent activity against the pathogen, and is palatable, and if the child has a social situation that will guarantee adherence. The switch to oral therapy should not occur before clinical response to intravenous therapy, including absence of fever, return to normal function, and a decrease or normalization of inflammatory markers. Oral antibiotics often require 2 to 3 times the usual dose to achieve adequate bone penetration, making gastrointestinal tolerance of high doses of the antibiotic a requirement. Therapy is sometimes prolonged by several weeks empirically.

An abscess must be drained surgically when detected or suspected. The lack of pus on aspiration should suggest that the site of aspiration may have been inaccurate, or pus may be present but too thick to pass through even a large-bore needle. Care must be taken not to miss infection. A clinical suspicion or failure of the patient to respond to nonoperative therapy is an indication for operative decompression. The risks of unnecessary surgery in the child who has an acute infection are far less than those of necessary surgery not performed. MRI can help locate and define the anatomy of the infection in children failing conservative therapy. Chronic osteomyelitis always requires surgical debridement to remove necrotic bone, and prolonged antimicrobial therapy that typically lasts 3 to 6 months, perhaps less but sometimes longer for complicated cases. As with acute osteomyelitis, much of the treatment for chronic osteomyelitis may be completed with oral antibiotics.

Complications for hematogenous osteomyelitis include deep vein thrombosis (DVT), with increased risk if the child is critically ill at presentation or has a positive blood culture, infection with MRSA, elevated

C-reactive protein, and central venous catheter in place. DVT should be considered if the patient develops pulmonary findings or has persistently positive blood culture. Long-term complications may include pathologic fractures, limb length discrepancy, and avascular necrosis. Risk factors for such complications include a delay in diagnosis greater than 1 week, newborn age, hip joint infection, infection with MRSA, and more than 3-day delay in treatment with appropriate antibiotic(s).

### WHEN TO REFER

The diagnosis of possible osteomyelitis requires thorough evaluation and usually includes consultation with radiology and orthopedic surgery. Discussing the specifics of the case with the radiologist can help focus the radiologic evaluation effectively. Consulting early with the orthopedic surgeon helps expedite aspiration of the bone or open drainage. Infectious disease specialists help organize the evaluation, begin therapy, and follow up with children who are discharged on home intravenous therapy and who have chronic disease.

### WHEN TO ADMIT

Children with acute osteomyelitis require admission to the hospital for rapid evaluation and to begin treatment. The initial evaluation can begin as an outpatient, when the diagnosis of osteomyelitis is not yet established, perhaps with complete blood count, blood culture, and radiograph. However, the physician must follow up closely and consider hospitalization as soon as the diagnosis becomes likely.

## Chapter 305

## OTITIS MEDIA AND OTITIS EXTERNA

Tina Q. Tan, MD

## OTITIS MEDIA

Otitis media, an inflammation of the middle ear, is the most common reason that children in the United States receive a prescription for antibiotic therapy. More than 90% of all antibiotic use in the first 2 years of life is attributable to the treatment of otitis media. By the age of 7 years, between 65% and 95% of children will be treated for at least 1 episode of otitis media. Because otitis media is such a prevalent condition, much attention is focused on the consequences and its treatment. Rare suppurative complications, such as intracranial abscess, can be serious. Conductive hearing loss resulting from chronic middle-ear effusions associated with otitis media may contribute to speech and language delay in some children. The overuse of antibiotics to treat otitis media may contribute significantly to the emergence of antibiotic-resistant bacteria. Each year in the United States, billions of dollars are spent on the treatment of otitis media alone. In response to growing concerns about the increasing rates of antibacterial resistance and the escalating costs of antibacterial prescriptions for the treatment of this disease, the American Academy of Pediatrics (AAP) and the American Academy of Family Physicians (AAFP) published an updated evidence-based clinical practice guideline on the diagnosis and management of acute otitis media in 2013. The major aim of this guideline is to focus attention on the need for the judicious use of antibacterial agents in the treatment of acute otitis media and update the recommendations based on the most current evidence supporting these guidelines. Despite this attention, the management of otitis media remains a source of debate in the medical literature.

## Classification

Otitis media encompasses several clinical entities. *Acute otitis media* (AOM) describes the presence of inflammatory fluid in the middle-ear space accompanied by the acute onset of local findings such as ear pain, otorrhea, or distortion of the tympanic membrane (eg, bulging, erythema, opacity, limited or absence of mobility). Systemic findings such as fever and irritability may also be present. *Otitis media with effusion* (OME), or serous otitis media, describes the presence of inflammatory fluid in the middle-ear space in an asymptomatic child, following an episode of AOM, or in a child with mild upper respiratory tract symptoms, a common reason for examining the ears in the first place. The term *recurrent otitis media* is generally used to refer to 3 or more episodes of AOM in 6 months or 4 episodes in 1 year, with 1 episode in the preceding 6 months. Recurrent otitis media should not be confused with chronic otitis media, which may be used to describe OME

that lasts longer than 3 months or a suppurative middle-ear process that fails to respond to initial antibiotic therapy. Specificity in diagnosis is important because of its significant implications for management.

## Epidemiologic Features

By the age of 1 year, almost two-thirds of children will experience at least 1 episode of AOM. Otitis media is more common in boys and in children of low socioeconomic status. Incidence rates in white and black children are very similar. Several environmental factors increase the risk for developing otitis media, including the winter season, exposure to tobacco smoke, use of a pacifier, and attendance at child care centers, particularly those serving large numbers of children.

In addition, any amount of breastfeeding reduces the incidence of otitis media by 23% and exclusive breastfeeding for more than 3 months reduces it by 50%. The 2013 AOM guidelines also suggest that physicians encourage exclusive breastfeeding for at least 6 months. Interestingly, Xylitol, or birch sugar, was associated with a 25% reduction of AOM among healthy children at child care centers. However, it is not an effective treatment of AOM because it needs to be given 3 to 5 times a day, as well as daily throughout the respiratory illness season. Obviously, children younger than 2 years of age cannot safely use lozenges or chewing gum, the forms in which is most effective.

Children at high risk for developing AOM include those with craniofacial anomalies (eg, cleft palate) that alter the normal air and fluid dynamics of the middle-ear space, those with immunodeficiencies, and those of certain ethnic groups such as Native Americans and Alaskan Natives. A mild hereditary predisposition to develop recurrent otitis media seems to exist, with some of the variation in presentation and incidence explained by genetic factors, whereas familial and individual environmental factors account for the remainder.

## Pathogenesis

Otitis media is an inflammatory process of the upper respiratory tract that usually results from a viral infection. As viruses infect the respiratory mucosa, edema can lead to eustachian tube dysfunction, so that inflammatory fluid and pathogenic respiratory bacteria that reflux into the middle-ear space do not drain normally. This process effectively leads to the formation of an abscess in the middle ear. Otitis media is usually self-limited; as the viral illness resolves, eustachian tube function is restored, and the middle-ear space drains normally. Although acute symptoms generally resolve spontaneously within a few days, middle-ear effusions can persist for weeks after an episode of AOM. In fact, 60% of middle-ear effusions resolve spontaneously within 3 months, whereas 85% resolve spontaneously within 6 months. The persistence of middle-ear effusions (or OME) after an episode of AOM has raised concern about the conductive hearing loss that accompanies these effusions and its effect on speech and language development, especially in younger children. These effusions are sterile and, in the absence of

other acute signs and symptoms, often do not require antibacterial therapy.

In studies of children with AOM, specimens of middle-ear fluid obtained by tympanocentesis are used to clarify the microbiologic mechanism of this disease. These specimens are positive for bacteria approximately 70% of the time: 55% with bacteria only and 15% with bacteria and viruses. The most frequently identified pathogens are *Streptococcus pneumoniae*, *Haemophilus influenzae* (increasingly  $\beta$ -lactamase producing), and *Moraxella catarrhalis*. Group A  $\beta$ -hemolytic streptococcus and *Staphylococcus aureus* (including methicillin-resistant strains) are much less common. Rarely, *Mycoplasma pneumoniae* is also detected but not often enough to affect the empirical selection of an antibiotic for treatment of AOM.

*H influenzae* has increasingly become a frequent isolate of middle-ear fluid since the introduction and use of 7-valent pneumococcal conjugate vaccine (PCV7) in 2000. Non-PCV7 serotypes are now just as common. *H influenzae* (nontypeable) is the most likely isolated pathogen causing AOM associated with conjunctivitis. The patterns of isolated pathogens continue to evolve with the continued use of the 13-valent pneumococcal conjugate vaccine that was introduced in 2010. Respiratory viruses such as respiratory syncytial virus (RSV), influenza viruses, and parainfluenza viruses are also recovered often from middle-ear aspirates, either in addition to bacteria or in isolation. Respiratory syncytial virus, in particular, has a tendency to infect the mucosa of the middle ear and probably contributes substantially to the development of otitis media in children.

### Diagnosis

Concern is growing that overdiagnosis of otitis media and liberal use of antibiotics for its treatment contributed to the rapid emergence of antibiotic-resistant bacteria, particularly penicillin-resistant *S pneumoniae*. Therefore, accurate diagnosis is critical to the appropriate management of otitis media. Diagnosis is based on recognition of the characteristic clinical context and physical findings on pneumatic otoscopic examination.

In the classic case of AOM, a young child with a history of a recent upper respiratory tract infection suddenly develops the acute onset of a new fever and ear discomfort. In children old enough to localize pain, the affected ear is often obvious. However, in younger children, discomfort may be more generalized with tugging, rubbing, or holding the ear, and they may exhibit unexplained or excessive crying, irritability, decreased appetite, or changes in their sleep or behavior pattern. Examination may reveal other signs of upper respiratory infection such as rhinorrhea, cough, or conjunctival injection.

The diagnosis of AOM is confirmed using pneumatic otoscopy. To perform this technique, the child must either cooperate or be restrained in a comfortable position that allows the examiner to manipulate the pinna and insert the otoscope into the external auditory canal without difficulty. Cleansing the external auditory canal must be accomplished to free it of obstructions so as to visualize the tympanic membrane;

cerumen or foreign bodies should be removed using a cerumen spoon or gentle irrigation with warm water or suction. The largest speculum that will fit into the external auditory canal at a depth of 1/3-inch to 1/2-inch should be attached to the pneumatic otoscope. This tool permits visualization of the largest possible area with a light source with adequate brightness and ensures a relatively airtight seal for effective insufflation.

Medical school and postgraduate training programs should provide continued education and clinical reinforcement with these techniques for appropriate use of pneumatic otoscopy. The use of training tools and educational resources, combined with Web-based images and video-otoscopes, is invaluable in the evaluation of the middle ear, the diagnosis of AOM, and the distinction between AOM and OME.

Acute otitis media is present when distortion (usually bulging) of the tympanic membrane is noted on direct visualization and when restricted movement of the tympanic membrane, indicative of fluid in the middle ear, is noted with gentle insufflation and exsufflation of air using a squeeze bulb attached to the otoscope. In addition, an air-fluid level behind the tympanic membrane may also be visualized. However, erythema of the tympanic membrane alone is not sufficient to make the diagnosis of otitis media and may be the incidental result of fever or crying. In some cases of AOM, the tympanic membrane may in fact be retracted rather than bulging.

Occasionally, a child with AOM may experience spontaneous rupture of the tympanic membrane, which subsequently leads to marked improvement in ear pain and the presence of otorrhea on examination.

OME may also be an incidental finding on physical examination and is characterized by decreased mobility of the tympanic membrane without the signs of acute inflammation seen in AOM.

In AOM, some experts advocate for making a specific bacteriologic diagnosis by obtaining middle-ear fluid for both culture and sensitivities using the technique of tympanocentesis or carbon dioxide laser-assisted myringotomy. These techniques are often not necessary for the routine diagnosis of AOM but are useful in specific clinical situations in which identification of an organism to guide therapeutic decisions is a high priority. These various situations may include episodes of AOM that do not respond to empirical antibiotic therapy, the child who experiences frequent recurrences of AOM despite what is thought to be appropriate therapy, and the child who is both young and particularly toxic in appearance.

Cultures of other areas of the upper respiratory tract are also useful for research purposes but do not assist in the management of these individual episodes of AOM. Organisms recovered from tympanocentesis or laser-assisted myringotomy specimens are usually also recovered from the nasopharynx, but the presence of an organism on solely a nasopharyngeal culture does not prove that it is present in the middle-ear fluid.

Tympanometry is a technique for documenting tympanic membrane compliance. It can be used to document objectively the presence of fluid in the

middle-ear space but does not add to the information obtained on carefully performed pneumatic otoscopy. Tympanometry measurements can be useful to monitor the course of an episode of OME over time.

## MANAGEMENT OF ACUTE OTITIS MEDIA

Whether an episode of AOM should be treated with antibiotics is a matter of ongoing discussion. The 2013 AAP and AAFP practice guidelines now delineate very specific criteria for which children should receive initial antibiotic therapy and which children should receive initial observation. Recent published studies provide substantial new research on initial management of AOM. The indications on whether to provide initial antibiotic therapy or the safety of observation or delayed antibiotic therapy are also included. Again, these guidelines on initial management assume the physician made an accurate diagnosis of AOM, which, of course, is of paramount importance.

Some of the acute symptoms of AOM, such as fever and ear pain, may resolve more quickly with antibiotic therapy. Early empirical antibiotic therapy may also obviate the need for follow-up office visits to evaluate the patient with otitis media who is not responding to expectant management. However, most episodes of AOM resolve spontaneously. Middle-ear effusions may persist despite effective antibiotic therapy, and rare suppurative complications are generally easily treated with antibiotics and surgical techniques. High-dose amoxicillin is the recommended first-line treatment for most children with AOM. It is used because it is inexpensive, safe, has an acceptable taste, and covers a narrow antimicrobial spectrum. In children with persistent, severe symptoms of AOM and unimproved otologic findings after 48 to 72 hours of amoxicillin therapy, a change to amoxicillin-clavulanate may be indicated. Amoxicillin-clavulanate is also indicated when concurrent purulent conjunctivitis is present. The modest benefits of antibiotic therapy also must be weighed against the negative effect of widespread antibiotic use and its effect on producing antibiotic-resistant species of organisms such as *S pneumoniae*. In some areas of the United States, up to 40% of strains of this organism are resistant to penicillin. Even though the use of PCV7 decreased the amount of antibiotic resistance seen by about 29%, there has been an emergence of a multidrug-resistant 19A strain of pneumococcus that may also cause otitis media. Still, *H influenzae* isolates are susceptible to amoxicillin in 58% to 82% of cases. This represents a significant decrease in  $\beta$ -lactamase-producing *H influenzae* compared with the 2004 AOM guideline.

Although optimal duration of AOM therapy is uncertain, for children younger than 2 years of age and those with severe symptoms, a standard 10-day course is recommended. However, for children between 2 and 5 years of age and with mild or moderate AOM, a 7-day course can be equally as effective. Finally, for children 6 years of age and older with mild to moderate symptoms, a 5- to 7-day course is sufficient.

The new 2013 AOM guidelines stress that the physician should do the following:

1. Prescribe antibiotic therapy for AOM (bilateral or unilateral) in children 6 months and older with severe signs or symptoms (ie, moderate or severe otalgia, otalgia for at least 48 hours, or temperature  $\geq 102.2^{\circ}\text{F}$  [ $\geq 39^{\circ}\text{C}$ ]).
2. Prescribe antibiotic therapy for bilateral AOM in children younger than 24 months without severe signs or symptoms (ie, mild otalgia for at least 48 hours, temperature  $< 102.2^{\circ}\text{F}$  [ $< 39^{\circ}\text{C}$ ]).
3. Either prescribe antibiotic therapy or offer observation with close follow-up based on joint decision making with the parent(s)/caregiver for unilateral AOM in children 6 to 23 months of age without severe signs or symptoms (ie, mild otalgia for at least 48 hours, temperature  $< 102.2^{\circ}\text{F}$  [ $< 39^{\circ}\text{C}$ ]). When observation is used, a mechanism must be in place to ensure follow-up and begin antibiotic therapy if the child worsens or fails to improve within 48 to 72 hours of onset of symptoms.
4. Either prescribe antibiotic therapy or offer observation with close follow-up based on joint decision making with the parent(s)/caregiver for AOM (bilateral or unilateral) in children 24 months or older without severe signs or symptoms (ie, mild otalgia for at least 48 hours, temperature  $< 102.2^{\circ}\text{F}$  [ $< 39^{\circ}\text{C}$ ]). When observation is used, a mechanism must be in place to ensure follow-up and begin antibiotic therapy if the child worsens or fails to improve within 48 to 72 hours of onset of symptoms.

Although there is no proven benefit for the use of antihistamine or decongestant preparations, steroids, acetaminophen, and nonsteroidal anti-inflammatory medications are effective analgesics for mild to moderate pain in the treatment of AOM. Also, topical agents such as Auralgan (antipyrine, benzocaine, and glycerin dehydrated) otic solution can provide additional brief benefit over acetaminophen in children older than 5 years of age.

When initial observation of AOM is warranted based on the above guidelines, it is essential to have an appropriate management strategy consisting of early analgesics, communication, and education about the self-limited nature of AOM in children 2 years and older and, of course, the option of a delayed antibiotic because of potential adverse effects, including diarrhea and diaper dermatitis. A mechanism must be in place to ensure follow-up and begin an antibiotic if the child fails observation.

## FOLLOW-UP AFTER ACUTE OTITIS MEDIA TREATMENT

Most children who respond satisfactorily to treatment of an episode of AOM do not require specific follow-up. As long as a child is asymptomatic, the main reason for follow-up is to document resolution of a middle-ear effusion that may contribute to conductive hearing loss. However, observation for initial management of AOM does not increase suppurative complications if follow-up is provided and delayed antibiotics are then begun for persistent or worsening symptoms. Withholding antibiotics to those who require them, as

detailed in the guidelines, would in fact increase the risk for suppurative complications. After 2 weeks of antibiotic therapy, 60% to 70% of children can have an effusion, whereas after 4 weeks, the percentage decreases to 40%, followed by 10% to 25% after 3 months of appropriate antibiotic therapy. Therefore, follow-up for the otherwise healthy and asymptomatic child should be scheduled no sooner than 6 weeks after diagnosis, if at all. An effusion that persists at 6 weeks does not warrant specific intervention other than perhaps checking for resolution again in 6 more weeks. Further management of an effusion that persists beyond this point is described in the treatment of OME.

In various systematic reviews before 2011 and a meta-analysis, there was a 6% to 14% increase in clinical improvement after antibiotic use, whereas other randomized clinical studies using stringent diagnostic criteria showed a clinical improvement rate between 26% and 35% compared with placebo. A clinically significant benefit of immediate antibiotic therapy is observed for bilateral AOM, *S pneumoniae* infection, or AOM associated with otorrhea. Still, clinicians should reassess the child within 48 to 72 hours to determine whether a change in therapy is needed if the parent(s)/caregiver reports that the child's symptoms are worse or failed to respond to the initial antibiotic treatment.

## MANAGEMENT OF OTITIS MEDIA WITH EFFUSION

Accurate diagnosis of OME is essential before being presented with a different therapeutic challenge than AOM. The goal of therapy for this disorder is to limit any potential long-term detrimental effects on speech and language development that may be caused by conductive hearing loss associated with the presence of a chronic middle-ear effusion. Weak associations have been found between OME and abnormal speech and language development in children younger than 4 years and problems with attention and expressive language delay in older children. However, these associations may be the result of environmental influences that predispose the child to both OME and developmental delays. However, the effects of treating OME on these outcomes, are not well established.

Medical therapies for OME produced largely unsatisfactory results. Although very limited scientific evidence exists, a few experts think that empirical antibiotic therapy either early in the course of OME or later, when the effusion persists for 3 months or more, may hasten resolution of the effusion. Most experts strongly discourage this practice, given the increasing rates of antibacterial resistance being seen. No role exists for steroid medications, antihistamine or decongestant preparations, or tonsillectomy or adenoidectomy in the management of OME. The most effective therapy for OME is the surgical insertion of tympanostomy tubes, which evacuates a middle-ear effusion and restores near-normal hearing, but the effect of this procedure on long-term speech and language outcomes is unclear. A newer technique, laser-assisted myringotomy, may soon replace tympanostomy tube placement for the treatment of OME.

When OME is documented in a child, subsequent follow-up at 3 months is reasonable, assuming acute symptoms did not intervene. If, at 3 months, middle-ear effusions persist and are bilateral, then referral for audiologic testing is indicated. If hearing is normal, then further observation to allow spontaneous resolution is appropriate. If a conductive hearing loss at a threshold of 20 dB or greater is documented at the 3-month follow-up, then consideration should be given to either tympanostomy tube placement or laser-assisted myringotomy to drain the effusions and restore hearing. However, the use of these procedures for OME in otherwise-healthy children with normal hearing is not recommended.

Adenoidectomy is used to manage patients with OME and may be effective in a select group of children. Chronically infected adenoids are thought to serve as a reservoir of pathogenic organisms that leads to tubal edema and malfunction, which may clinically produce persistent OME. The removal of enlarged adenoids has improved effusion resolution. In the otolaryngology literature, adenoidectomy and myringotomy plus ventilation tube insertion is recommended therapy for children with severe ear disease and those undergoing replacement of a second set of ventilation tubes.

## MANAGEMENT OF RECURRENT OTITIS MEDIA

The occurrence of 3 or more episodes of AOM within 6 months or 4 episodes within a year with 1 episode in the preceding 6 months satisfies many experts' definition of recurrent or chronic otitis media. The therapy of recurrent otitis media is also controversial. Past studies showed that long-term administration of prophylactic antibiotics can reduce the incidence of subsequent episodes of AOM in these children; however, the effect is modest at best. Even long-term, low-dose antibiotic use (antibiotic prophylaxis) prevents 1.5 episodes of AOM per year. However, an estimated 5 children would need to be treated for 1 year to prevent 1 episode of otitis media, specifically in children with 6 or more episodes of AOM in the preceding year. Therefore, according to the 2013 AOM guidelines, the use of prophylactic antibiotics is currently not recommended for management of recurrent otitis media. Controlling environmental risk factors such as exposure to tobacco smoke and attendance at large child care centers is a more desirable approach to this problem.

Tympanostomy tube placement or laser-assisted myringotomy should be considered in the management of recurrent otitis media. This approach may be justified when recurrent AOM complicates OME and is accompanied by hearing loss. However, frequent episodes of AOM (without OME) that respond to appropriate antibiotic therapy are not an indication for these procedures. Although AOM does tend to occur less frequently in children who have tympanostomy tubes, this approach is a surgical procedure requiring anesthesia, and the tubes may not remain in place for a sufficient duration to have a measurable effect on the health of a child. Recent literature does suggest that insertion of tympanostomy tubes or

long-term treatment with antibiotics seems to prevent 1 attack of AOM or to keep 1 out of 3 children from developing AOM in the ensuing 6 months.

Use of a conjugated vaccine against *S pneumoniae*, widespread use of the influenza vaccine in healthy children (where many studies show a 30% to 55% efficacy rate in prevention of AOM during the respiratory illness season), and development of an effective vaccine against RSV are all strategies that show promise for preventing future episodes of otitis media.

## CARE OF THE CHILD WITH TYMPANOSTOMY TUBES

Tympanostomy tube placement is the most common surgical procedure performed in children. In fact, all physicians who care for children will encounter tympanostomy tubes in their practice. Examination of the child with tympanostomy tubes should show a patent tube traversing the pars flaccida. Because the tympanic membrane that contains a tympanostomy tube is not intact, its mobility is affected, and pneumatic otoscopy cannot be used as a reliable indicator of the presence of AOM.

Tympanostomy tubes are usually extruded naturally sometime after insertion. Some otolaryngologists recommend actively removing tympanostomy tubes that are in place for 2 or more years to prevent complications such as chronic perforation or tympanosclerosis. If a tympanostomy tube is visualized in the external canal and is no longer seated within the tympanic membrane, then it may be removed carefully with a cerumen spoon under direct visualization.

Occasionally, a granuloma may develop at the site of tympanostomy tube insertion, which can lead to bleeding from the external auditory canal. When this event occurs, these children should be immediately referred to an otolaryngologist for intervention.

Otorrhea is extremely common in children with tympanostomy tubes. Otorrhea associated with other symptoms of upper respiratory infection may indicate the presence of AOM and should be treated accordingly. When otorrhea occurs in isolation, it may respond to topical application of an otic solution containing neomycin, polymyxin B, and hydrocortisone. Otorrhea is no more common in children with tympanostomy tubes who swim or submerge their heads in a bathtub than it is in those who do not engage in these activities. The use of topical antibiotics or earplugs does not reduce the incidence of swimming-related otorrhea. Children with tympanostomy tubes who do not dive to depths of greater than 6 feet nor swim in potentially contaminated water (such as a pond) require no additional special precautions to swim, and the use of earplugs or molds may actually increase drainage from the ears.

## COMPLICATIONS

The most worrisome suppurative complications of otitis media include mastoiditis, intracranial extension of infection, and lateral sinus thrombosis. These complications are rare and occur much less frequently than in the era before routine antibiotic treatment of AOM. Interestingly, the incidence of these complications declined in areas of the world where routine

antibiotic treatment of AOM is less common, suggesting that factors other than early antibiotic treatment may have contributed to this trend.

Recognizing the early signs and symptoms associated with suppurative complications of otitis media is of the utmost importance so that effective medical or surgical therapy can be instituted promptly. These signs and symptoms may include mastoid tenderness, erythema over the mastoid area with swelling and displacement of the pinna, persistent fever associated with chronic tympanic membrane perforation, persistent and severe headache, severe otalgia, retro-orbital pain on the side of the affected ear, vertigo, mental status changes, and nystagmus. Other focal neurologic signs such as facial paralysis, meningismus, and papilledema can also signal intracranial extension of suppurative otitis media.

## OTITIS EXTERNA

Otitis externa (OE) is an inflammatory process that involves the structures of the outer ear, specifically the external auditory canal. It is a common finding in children, especially during the warm-weather months of the year. However, the site of the inflammation is different from otitis media, and the signs and symptoms associated with OE differentiate this condition.

Otitis externa is multifactorial in etiology and often involves an interaction between both host and environmental factors. Some of these factors may include trauma to the external auditory canal, the presence of a foreign body or glandular obstruction, repeated ear cleansing causing loss of the canal's protective coating, prolonged exposure to standing water in the canal that occurs following swimming or bathing (swimmer's ear), high environmental temperature and humidity often leading to increased sweating, and allergy or continued stress. Inflammation may be either focal, at the site of trauma or an infected hair follicle, or diffuse, as is the case with swimmer's ear. When inflammation is focal and associated with infection, the organism most often is *S aureus*, which can ultimately lead to furuncle formation at the site of the inflammation. The most common organism associated with diffuse inflammation is *Pseudomonas aeruginosa*, a hydrophilic bacterial species. Infection is often polymicrobial, and enteric bacilli or fungi are less common causes of OE.

Children with OE complain of ear pain and may also report pain with chewing (owing to the proximity of the temporomandibular joint to the external auditory canal) and difficulty hearing (owing to swelling within the external auditory canal and conductive hearing loss).

Physical examination reveals tenderness with manipulation of the pinna or pressure on the tragus. Insertion of an otoscope into the external auditory canal can also be painful and should be undertaken carefully. Within the canal, focal erythema and swelling may be seen at a site of trauma or folliculitis. If the inflammation is diffuse, then swelling of the entire canal renders a boggy appearance. Edema and the presence of inflammatory debris may subsequently prevent complete visualization of the tympanic membrane, which should seem normal in cases of OE unless coexistent otitis media is also present.

## MANAGEMENT

Diffuse OE usually responds to application of an ototopical antimicrobial-steroid solution containing neomycin, polymyxin B, and hydrocortisone 4 times a day for 7 to 10 days. With the child lying on the unaffected side, 5 drops of this solution are instilled into the affected ear. The child should remain in this position for 5 to 10 minutes after instillation to ensure that the medication comes in contact with the affected skin. Insertion of a cotton wick can help prolong this contact. Moreover, when OE is accompanied by furuncle formation, incision and drainage may be necessary. Otitis externa, on the other hand, can be prevented by keeping the external auditory canal dry and by avoiding vigorous cleaning of the canal that can ultimately lead to superficial trauma.

## MALIGNANT OTITIS EXTERNA

Malignant OE is a complicated form of OE that can develop in immunocompromised children or those with severe malnutrition. It is a necrotizing invasive infection of the external auditory canal, often beginning as minor trauma to the canal, usually caused by *P aeruginosa*, which rapidly spreads to involve the soft tissue, cartilage, nerves, and temporal bone, leading to osteomyelitis of the base of the skull. The pain is severe, and the discharge from the external canal is often copious and malodorous in nature. Children may develop facial paralysis, which is a poor prognostic sign. Diagnosis can often be made by both clinical signs and imaging. Triphasic bone and gallium scintigraphy examinations are often used, but studies suggest that single-photon emission computed tomography images are even more sensitive. Treatment requires administration of intravenous antibiotics and, occasionally, surgical intervention, with close follow-up; erythrocyte sedimentation rate can be used as a good indicator of treatment response. Complications of malignant OE include stenosis of the external auditory canal, auricular cartilage deformity, tympanic membrane necrosis, and sensorineural hearing loss.

## WHEN TO REFER

Patients with recurrent or chronic otitis media or persistent OME (present for at least 3 months) should be referred to an ear, nose, and throat (ENT) specialist for further evaluation. In addition, an infectious diseases consultation should be obtained in children with the following conditions:

- Suppurative complications of otitis media
- Recurrent or chronic episodes of otitis media unresponsive to standard therapy
- Unusual or multiple antibiotic-resistant organisms isolated from middle-ear fluid
- Chronic suppurative otitis media unresponsive to conventional therapy
- Malignant OE

In many of the these conditions mentioned, a multidisciplinary team approach with both ENT and infectious diseases referrals should be used for optimal management of the patient's condition.

## WHEN TO ADMIT

- Children with severe otitis media who are toxic in appearance, children with malignant OE, and children with suppurative complications of otitis media (as briefly described) should be admitted to the hospital. This allows the institution to promptly and effectively administer intravenous antibiotic therapy and further evaluate for possible surgical intervention.

## TOOLS FOR PRACTICE

### Community Advocacy and Coordination

## Chapter 306

# PANCREATITIS

James E. Squires, MD, MS; Samuel A. Kocoshis, MD

## FOUNDATION

### Definition

Pancreatitis in children is a disorder characterized by inflammation of the pancreas in the clinical setting of epigastric abdominal pain. An elevation of pancreatic enzymes (amylase and lipase) in the serum or urine is common. Pancreatitis in children and adolescents is often divided into 2 broad categories: acute and chronic. Acute pancreatitis is a reversible process with complete resolution of the inflammatory reaction and return of normal pancreatic endocrine and exocrine function. Chronic pancreatitis may ultimately result in irreversible changes in glandular histopathology (fibrosis) and pancreatic dysfunction. The incidence of acute pancreatitis is much higher than chronic pancreatitis. The most prevalent causes of acute pancreatitis in children are idiopathic, blunt abdominal injury, pancreaticobiliary disorders, multisystem disease, infection, autoimmune disease, and drug toxicity. Chronic pancreatitis, characterized by a more prolonged and recurrent course, occurs in about 9% of children who present with acute pancreatitis and is often hereditary or results from congenital anomalies of the pancreatic gland or biliary ductal system.

Pancreatitis can also be categorized according to its histopathologic findings. Edematous changes often correlate with mild disease, whereas evidence of hemorrhagic or necrotic changes signifies a more severe process with increased morbidity and mortality or irreversible gland dysfunction. A diagnosis of hemorrhagic or necrotic pancreatitis is an appreciated end product of the inflammatory process and gland destruction. It is primarily based on direct tissue visualization or radiographic imaging and often does not account for the underlying cause of the pancreatic inflammation. Although the prevalence of pancreatitis in children seems to be increasing, much of the literature concerning pancreatic disease remains concentrated in the adult and surgical populations.

### Epidemiology

Although once considered a relatively uncommon diagnosis in children, the prevalence of pediatric pancreatitis has steadily risen over the past several years and now approaches that seen in adults.

Currently, the best estimates suggest that there are 3.6 to 13.2 pediatric cases per 100,000 individuals per year.

Acute pancreatitis seems to account for much of the increase. The diagnosis of idiopathic pancreatitis has risen sharply compared with other known causes of acute pancreatitis. The prevalence of chronic pancreatitis has remained relatively constant, but pancreaticobiliary anomalies are now recognized as the most common cause of recurrent pancreatitis in children. Other causes such as hereditary pancreatitis are recognized more often as well. Factors likely contributing

to the increased prevalence include better physician awareness, increased disease, enhanced imaging techniques, and alterations in referral patterns. Additionally, survival rates for children with complicated systemic diseases have increased, and this population may be at increased risk for developing pancreatitis secondary to ischemic or anoxic injury or underlying inflammatory processes. Despite this increasing prevalence, pancreatitis in children continues to be underdiagnosed. Many children with chronic pancreatitis have been symptomatic for years before a firm diagnosis is made. Thus, the pediatrician faced with a patient who has epigastric abdominal pain should harbor a high index of suspicion for pancreatitis.

### Etiology

Causes of pancreatitis in children differ dramatically from causes in adults. Alcohol and gallstone disease are the most common etiologies in adults, but they are rare causes of pancreatitis in children. Although 16 causes were reported in 1965, up to 80 etiologic considerations have been described in the subsequent years (see Box 306-1). Idiopathic and traumatic causes are the most common, followed by structural and multisystemic causes of pancreatitis. These account for nearly two-thirds of all cases. In most children, pancreatitis is a single event without recurrence. However, in some subpopulations, such as children with cystic fibrosis, those with hereditary pancreatitis, and those with pancreatitis secondary to congenital structural malformations, the pattern of inflammation often develops into one of chronicity.

### Risk Factors

Trauma, structural abnormalities, and multisystemic disease are the most common causes of pancreatic inflammation in children. It is important to determine the cause of pancreatitis so that appropriate preventive, diagnostic, and therapeutic measures can be instituted. Advances in the fields of genetics and DNA sequencing have allowed investigators the ability to identify at-risk populations of children who, because of genetic mutations and variation, are at increased risk for the development of hereditary pancreatitis. Although cystic fibrosis and the *CFTR* mutation are recognized as the most common cause, other identified genetic mutations that have been associated with the development of chronic pancreatitis in children include the *SPINK1* mutation (also known as *PSTI*), mutations in the trypsinogen gene (R122H, R122C, and N29I accounting for most cases), and the *CaSR* mutation. Increasingly, evidence suggests that the likelihood of developing pancreatitis is because of a combination of environmental and genetic factors. Identifying those children who may be more genetically susceptible to developing pancreatitis may assist pediatricians in counseling to avoid known precipitating factors such as alcohol, tobacco, emotional stress, and fatty foods.

The onset of acute pancreatitis is associated with certain medications (most commonly, valproic acid), systemic infections (bacterial and viral), and hypertriglyceridemia. Of particular interest, in view of the growing obesity epidemic, is the association between elevated triglyceride levels and the development of acute pancreatitis. Marked elevations in triglyceride

**BOX 306-1 Conditions Associated With Acute and Chronic Pancreatitis in Childhood****INFECTIONS**

- *Ascaris lumbricoides* (duct obstruction)
- *Campylobacter fetus*
- *Clonorchis sinensis* (duct obstruction)
- Coxsackie B virus
- Cytomegalovirus
- Echovirus
- Enterovirus
- Epstein-Barr virus
- *Escherichia coli*-verotoxinproducing
- Hepatitis A and B
- Human immunodeficiency virus
- Influenza A and B
- Legionnaire disease
- Leptospirosis
- Malaria
- Measles
- Mumps
- *Mycoplasma*
- Rubella
- Rubeola
- Typhoid fever
- Varicella
- *Yersinia*

**TRAUMA**

- Abdominal radiotherapy
- Accidental blunt injury
- Burns
- Child abuse
- Endoscopic retrograde cholangiopancreatography or other ductal imaging using contrast
- Surgical trauma
- Total body cast

**ANATOMIC**

- Absence or anomalous insertion of the common bile duct or pancreatic duct
- Ampullary disease: diverticulum, stenosis
- Annular pancreas
- Anomalous choledochopancreaticoductal junction
- Aplasia of the pancreas
- Biliary tract malformations
- Choledochal cyst
- Choledochoceles
- Cholelithiasis
- Duodenal obstruction (diverticulum, hematoma, tumor, stricture)
- Duodenal ulcer-perforated
- Duplication cyst (duodenum, gastropancreatic, common bile duct)
- Dysplasia of the pancreas

- Gastric trichobezoar
- Heterotopic pancreas
- Hypoplasia of the pancreas
- Pancreas divisum
- Pancreatic pseudocyst
- Sclerosing cholangitis
- Sphincter of Oddi dysfunction
- Tumors of the pancreas

**IDIOPATHIC**

- Up to 25% of cases

**SYSTEMIC/METABOLIC/HEREDITARY**

- Alpha-1-antitrypsin deficiency
- Anorexia nervosa
- Autoimmune diseases
- Brain tumor
- Bulimia
- Collagen vascular diseases
- Congenital partial lipodystrophy
- Crohn disease
- Cystic fibrosis
- Dermatomyositis
- Diabetes mellitus (ketoacidosis)
- Glycogen storage disease types Ia, Ib
- Head trauma
- Hemochromatosis
- Hemolytic-uremic syndrome
- Henoch-Schönlein purpura
- Hereditary pancreatitis
- Hyperalimentation
- Hypercalcemia
- Hyperlipidemia types I, IV, and V
- Hyperparathyroidism
- Hypertriglyceridemia
- Hypothermia
- Inborn errors of metabolism (organic acidemias, cytochrome c oxidase deficiency)
- Juvenile tropical pancreatitis
- Kawasaki disease
- Malnutrition with or without refeeding
- Periarteritis nodosa
- Peritonitis
- Renal failure with uremia
- Reye syndrome
- Sarcoidosis
- Septic shock
- Systemic lupus erythematosus
- Transplantation (bone marrow, heart, kidney, liver, pancreas)
- Ulcerative colitis
- Wilson disease

**BOX 306-2 Conditions Associated With Elevated Serum Amylase****FROM PANCREATIC AMYLASE FRACTION**

- Aortic aneurysm—abdominal
- Appendicitis

- Renal insufficiency
- Renal transplantation
- Ruptured ectopic pregnancy

levels (typically  $>1,000$  mg/dL) seem to be linked to development of acute pancreatitis, and although the mechanism underlying the relationship is ill defined, hypertriglyceridemia occurs in 12% to 38% of adult pancreatitis cases. Although there is insufficient literature describing the relationship between triglyceride elevations and pancreatitis in children, pediatricians should be aware of known associations present in the adult population as they increasingly manage historically adult illnesses now present in children.

**DIAGNOSIS****Signs and Symptoms**

Despite expanding etiologies and increased physician awareness, initial presentation of pancreatitis has changed very little since it was first recognized decades ago. Almost all patients diagnosed with pancreatitis present with upper abdominal pain and tenderness at the onset. The abdominal pain is often mid-epigastric in location or located to either the left or right upper quadrants, with the classic radiation to the back seen in some patients. Concomitant symptoms include nausea, vomiting, low-grade fever, and worsening of pain with eating. Additionally, increased agitation and relief of pain with the child in the antalgic position with hips and knees flexed, sitting in the upright position, or lying on the side can be seen. The age and expressivity level of the child, as with many other diseases, often complicate the initial presentation of pancreatitis, especially in younger children. Many infants and toddlers cannot effectively communicate or quantify the subjective feelings of nausea and abdominal pain. Complicating the clinical picture of a young child with pancreatitis is the finding that many younger children present with a more atypical picture and may

not have the classic abdominal pain, tenderness, or nausea seen in older children and adults. In such cases, a high index of suspicion is required to uncover the diagnosis, especially when there is a history of abdominal trauma, accidental or otherwise.

In cases of severe pancreatitis, symptoms can be particularly impressive. Elevated fevers, signs of shock, jaundice, and pleural effusions can occur. Hemorrhagic or necrotic pancreatitis may present in the setting of bluish discoloration around the umbilicus (Cullen sign) or the flanks (Turner sign). Although rare, hemorrhagic or necrotic pancreatitis often predicts a more severe clinical course, with multisystem inflammatory responses as well as multiorgan dysfunction.

**Differential Diagnosis**

The differential diagnosis for pancreatitis is often quite broad because many times the nonspecific symptoms of abdominal pain, nausea, and vomiting are the only presenting complaints. The diagnosis of pancreatitis is often made only after more common causes of the presenting symptoms have been considered, such as acute gastroenteritis, appendicitis, mesenteric adenitis, and urinary tract infections. However, in the setting of severe pancreatitis with dramatic clinical presentations, it is imperative that the differential diagnoses be expanded to include other etiologies such as perforated viscus, acute peritonitis, biliary tract disease, and intestinal obstruction.

Additionally, laboratory data are often integral in the diagnosis of pancreatitis in children, particularly when elevations in the pancreatic enzymes, amylase and lipase, are appreciated in the serum or urine. Importantly, a multitude of other disease processes can lead to elevations in the pancreatic enzymes

**Table 306-1** Common Laboratory Values in Acute Versus Chronic Pancreatitis

	ACUTE PANCREATITIS	CHRONIC PANCREATITIS
Complete blood count	Leukocytosis with bandemia hemoconcentration	Usually normal
Renal (glucose)	Hyperglycemia, hypocalcemia	May have elevated glucose
Liver function	Elevations in ALT, AST, alkaline phosphatase, total bilirubin	Elevated in patients with concomitant liver disease or bile obstruction
Amylase/lipase	Elevated (generally use 3–6 times the upper limit of normal)	Normal or slight elevation

(particularly amylase), and pediatrician awareness is critical to correctly diagnosing and appropriately directing treatment (Box 306-2).

### Diagnostic Approach

A thorough history and physical examination are crucial to the initial management of a child suspected of having pancreatitis and will help direct additional laboratory and imaging studies. Family history is also important because hereditary pancreatitis is often transmitted as an autosomal dominant trait with incomplete penetrance. However, given the nonspecific qualities of the presentation (abdominal pain, nausea, emesis), laboratory data and radiologic studies are often an integral part of the diagnostic approach.

### Laboratory Findings

Results of laboratory evaluation can greatly assist the pediatrician in the diagnoses of pancreatitis. A complete blood count with differential, renal panel with glucose, liver function studies, and pancreatic enzymes (amylase and lipase) are often obtained in the initial investigation (see Table 306-1). Amylase, an enzyme that breaks down starch to sugar, is the test used most often to confirm acute pancreatitis despite its relatively low sensitivity and specificity (75%–92% and 20%–60%, respectively). Amylase levels reaching 3 times the upper limit of normal are often used as diagnostic cutoffs for pancreatitis. Serum activity begins to increase 2 to 12 hours after pancreatic injury and peaks at 12 to 72 hours. Hyperamylasemia is not diagnostic of pancreatitis and may be secondary to various disease processes in the salivary gland, intraabdominal pathology, or systemic disease. In postmenarchal females, it may herald pregnancy. Laboratories now can separate amylase isoenzymes into pancreatic and salivary fractions so as to assist in differentiating the etiology of the elevated amylase level. However, fractionation is a specialized test, and long turn-around time for results may preclude its usefulness in the acute setting.

In contrast to amylase, serum lipase is almost exclusively derived from the pancreas. It is an enzyme that breaks down dietary fats and converts triglycerides to monoglycerides and free fatty acids and should be obtained in addition to amylase when pancreatitis is suspected. During the course of acute pancreatitis, serum lipase rises by 4 to 8 hours, peaks at 24 to 48 hours, and remains elevated longer than serum amylase.

Despite its high specificity, serum lipase can be elevated in nonpancreatic diseases such as acute cholecystitis, intestinal infarction, perforated peptic ulcer disease, and renal failure.

It is important for the treating pediatrician to be aware that serum levels of these laboratory values are dependent on the chronicity of the inflammatory process and may differ dramatically based on the clinical picture. For example, patients with chronic pancreatitis moving toward glandular insufficiency may experience exacerbations of acute pancreatitis with relatively low serum levels of both amylase and lipase. Indeed, enzymes are often normal even during attacks of pain. Therefore, a normal amylase or lipase level should not exclude the diagnosis in a child with a positive history of pancreatitis.

The gold standard for establishing a diagnosis of chronic pancreatitis is glandular insufficiency. Assessing this involves invasive and direct testing of pancreatic function. Although there are noninvasive tests to assess pancreatic function (decreased serum pancreatic enzymes and fecal assays for fat and pancreatic enzymes), the negative predictive value often limits their interpretation. Additionally, false-positive results may be obtained in the presence of intestinal overgrowth or other mucosal disease. Therefore, true establishment of pancreatic insufficiency often involves oroduodenal or endoscopic intubation, accurate placement of a duodenal catheter, and complete recovery of all duodenal secretions. The difficulty of such testing usually means that their availability is limited to tertiary centers.

Other laboratory abnormalities that may be present in acute pancreatitis include coagulopathy, glucosuria, hypocalcemia, elevated  $\gamma$ -glutamyl transpeptidase, and hyperbilirubinemia.

Recent literature suggests that certain biochemical markers may be useful in predicting the severity and progression of acute pancreatitis, although, being nonspecific, they are not useful in the initial diagnosis. These markers include C-reactive protein (CRP), interleukin-6 (IL-6), and procalcitonin. CRP remains the most useful. Despite its delayed increase, peaking not earlier than 72 hours after the onset of symptoms, it is accurate and widely available. Also helpful is IL-6, which rises in severe pancreatitis in comparison with mild disease as early as the day of admission to the hospital, with peak concentrations on day 3 after the clinical onset of the disease.

Additional markers requiring further investigation include serum amyloid A, trypsinogen activation peptide (TAP), and polymorphonuclear granulocyte (PMN) elastase. Additionally, immunoglobulin G4 elevations may be more specific for autoimmune pancreatitis. Physician awareness of potential biomarker relationships with particular disease etiology is important when directed treatments (such as steroids for autoimmune disease) depend on the underlying causation mechanisms.

Genetic testing may also be indicated in particular patient populations. The most important clinical clue predicting the presence of hereditary pancreatitis is the presence of disease in other family members. Advances in genetics have allowed identification of multiple genetic mutations associated with hereditary pancreatitis. In general, genetic testing can be considered diagnostic or predictive. Diagnostic tests for hereditary pancreatitis are often obtained to determine genetic causes of a patient's pancreatitis, whereas predictive testing occurs in patients without evidence of disease, but who may have relatives with known pancreatitis or genetic susceptibilities to developing pancreatitis. In general, the clinical indications leading to diagnostic testing validate its use, but the role of predictive testing is more controversial.

### Imaging

Along with laboratory data, imaging plays a crucial role in the diagnosis of acute and chronic pancreatitis in children. The most common radiographic studies currently obtained in the evaluation of a child suspected of pancreatitis are ultrasound and computed tomography (CT) owing to their widespread availability, noninvasiveness, and familiarity to physicians. Because ultrasound exposes a child to dramatically less radiation, it is often the initial imaging modality. Smaller patient size with less fatty tissue, along with prominence of the left hepatic lobe, allows ultrasound of the pancreas in children to be more feasible. Furthermore, advances in ultrasound technology, such as high-resolution imaging, color Doppler, and harmonic imaging, have allowed for improved images and better diagnostic capabilities. Findings on ultrasound consistent with pancreatitis include glandular edema, hyperechogenicity, and pancreatic ductal dilation. Pancreatic ducts with diameters greater than 1.5 mm in children between ages 1 and 6 years, greater than 1.9 mm at ages 7 to 12 years, or greater than 2.2 mm at ages 13 to 18 years are significantly associated with the presence of pancreatic inflammation. Additionally, ultrasound is useful in detecting both etiologies and complications associated with pancreatitis such as gallstones, pseudocysts, and splenic vein thrombosis.

CT scans are often obtained as well in the evaluation of pancreatitis, especially if the ultrasound findings are nondiagnostic. However, CT scans do expose children to significant amounts of radiation. Additionally, animal models have shown that CT contrast given early in the course of acute pancreatitis may decrease blood flow to already ischemic areas of the pancreas and may worsen necrosis. Although validation studies have yet to be done in children, physicians should well consider whether the information obtained via the scan is likely to influence the medical management.

Another imaging modality increasingly used to assess a child with pancreatitis is magnetic resonance cholangiopancreatography (MRCP). MRCP can complement endoscopic retrograde cholangiopancreatography (ERCP) (see Diagnostic Procedures) in more complicated pancreatitis for which additional investigation of ductal anatomy may be needed. The advantages of MRCP over ERCP is that it is noninvasive, does not use radiation, is able to visualize the

pancreatic parenchyma, and can visualize pancreatic ducts as small as 1 mm both proximal and distal to any potential obstructive lesion. Additionally, the polypeptide hormone secretin can be given to patients to increase pancreatic duct signal for improved studies. The limitations to MRCP are that results have been shown to vary based on patient body habitus, patient cooperation and ability to remain still (often requiring sedation), and the medical center's experience with this study. Both an antiquated scanner and misinterpretation of information can limit the value of MRCP.

### Diagnostic Procedures

Endoscopic retrograde cholangiopancreatography is a technique that combines the use of endoscopy and fluoroscopy to diagnose and treat certain problems of the biliary or pancreatic ductal systems. Historically, ERCP has been used in the setting of pancreatitis to better understand an individual's anatomy and help visualize the ductal system (Figure 306-1).

Often ERCP is useful in the diagnoses of pancreatic disease associated with anatomic variations (such as pancreas divisum) or when biliary obstruction is suspected. The main advantage of ERCP over other imaging modalities is the ability to treat an anatomic obstruction at the time of procedure. Examples of therapeutic procedures include sphincterotomies, stone removal, and stent placement in either the biliary or pancreatic ductal system. Additionally, ERCP with glandular drainage has been shown to decrease the frequency of episodes of pancreatitis requiring hospitalization in certain populations, such as those with cystic fibrosis. ERCP seems to be an effective and safe procedure in children, with cannulation rates and visualization of the pancreaticobiliary duct anatomy comparable with those achieved in adults. Complications of ERCP are iatrogenically induced pancreatitis, with up to 11% of procedures developing a clinical picture of pancreatitis. Additionally, asymptomatic hyperamylasemia has been seen in up to 70% of patients after

**Figure 306-1** Endoscopic retrograde cholangiopancreatography image representing irregularity and beading of the pancreatic duct associated with chronic pancreatitis.

the procedure. The recent advances in MRCP have prompted the National Institutes of Health state-of-the-science statement to advise “no role [for ERCP] in the diagnosis of acute pancreatitis except when biliary pancreatitis is suspected.” Consequently, MRCP, with its noninvasiveness and lack of radiation, has the potential to supplant ERCP as an initial diagnostic modality, with the latter reserved as an interventional tool.

Although rare, pancreatic biopsies can be obtained, usually in patients with more chronic clinical courses. Such biopsies provide critical information when a diagnosis such as autoimmune pancreatitis is suspected (characteristic dense lymphoplasmacytic infiltration and fibrosis). Research is needed to better assess the benefits of direct tissue evaluation. Potential benefits are a more specific categorization and stage of chronic pancreatitis, ultimately leading to more targeted and directed therapies.

### Classification

Pancreatitis in children is broadly divided into acute and chronic entities whereby acute pancreatitis is a reversible process without long-term sequelae and chronic pancreatitis is a recurrent disease that ultimately results in changes in histology (fibrosis) and glandular dysfunction—both endocrine and exocrine. Future patients may benefit from a more formal classification system, especially those children diagnosed with chronic pancreatitis, for which a more complete understanding of an individual’s degree of pancreatic dysfunction may help develop more targeted therapies.

## MANAGEMENT

### Treatment Approach

In general, treatment of pancreatitis in children does not differ from that of adults. In children with acute pancreatitis, supportive treatment typically dominates early in the clinical course with fluid hydration, pain control, and “gland rest.” Historically, gland rest consisted of making a patient *nil per os* (NPO) with intravenous fluid support, followed by the slow reintroduction of food as the disease course allowed. When foods are tolerated, carbohydrate-rich foods are introduced first because they place less strain on the inflamed pancreas. If *per os* (PO) intake is not tolerated, total parenteral nutrition (TPN) can be initiated by days 3 to 5 of illness. Although discrepancies in the literature persist, it seems as though intravenous lipids included in the TPN are safe and beneficial, as long as triglyceride levels are monitored closely. However, it is widely accepted that enteral nutrition is preferred over parenteral nutrition. Recent studies in adults have assessed jejunal feeds and have shown good tolerance by most patients with uncomplicated disease. Such therapy allows for gut stimulation while preventing gastric and intestinal phases of pancreatic secretion, therefore preserving gland rest. Although certain complications, such as persistent vomiting or ileus, may prevent placement of a feeding tube and tolerance of jejunal feeds, enteral nutrition should be first-line therapy when possible. Regardless of method, it is imperative that patients with a more severe clinical

course receive some form of nutritional support because of the inherently elevated level of stress and hypercatabolism associated with pancreatitis.

Pain control typically constitutes the remainder of the initial therapy. Morphine is often avoided because of its known effects on the sphincter of Oddi, mainly spasm, and the theorized exacerbation of the patients’ abdominal pain. However, recent evidence does not support opioid avoidance and it is often used clinically. Hydromorphone (Dilaudid) and meperidine are commonly used alternatives to opioids. Meperidine has been shown to lower seizure thresholds in susceptible patients and should be used sparingly in such populations.

After supportive therapies have been implemented, the clinical course often directs additional treatment. As previously noted, although most children with pancreatitis follow a relatively predictable clinical course, certain patients do go on to develop severe complications with the development of shock, systemic inflammatory responses, sepsis, and multiorgan dysfunction. Such patients require escalated medical management, often with antibiotics, aggressive fluid management, respiratory support, and monitoring in intensive care units. The ability to predict which children are at risk for developing such severe clinical courses has been elusive. In the adult population, several prognostic systems have been developed and validated to predict clinical severity. The most widely used are the Ranson criteria, Glasgow Coma Scale, modified Glasgow Coma Scale, and Acute Physiology and Chronic Health Evaluation (APACHE) II score. Despite their clinical utility in adults, these prognostic scoring systems have not been validated in children. Loosely based on the Ranson criteria, recent literature has attempted to develop a prognostic scoring system for children. The scoring system was based on parameters obtained at admission and 48 hours after the onset of illness. Criteria assessed at admission included age younger than 7 years, weight less than 23 kg, white blood cell count higher than 18,500, and lactate dehydrogenase (LDH) level greater than 2,000. The 48-hour criteria were trough calcium less than 8.3 mg/dL, trough albumin less than 2.6 mg/dL, fluid sequestration more than 75 mL/kg per 48 hours, and rise in blood urea nitrogen more than 5 mL/dL. As with the Ranson criteria, patients were given 1 point for each criterion met, with scores assessed at admission and at 48 hours of illness. Ultimately, the authors concluded that children who have a score of zero on admission and during the first hours of illness have the lowest probability of developing severe disease and suggested these patients should be admitted to routine ward beds. Children with scores greater than or equal to 3 on admission should be admitted to the intensive care unit (ICU) for intensive monitoring. Children with intermediate scores need admission and close monitoring with a low threshold for transfer to the ICU if scores increased to 3 parameters or more. Clearly, more research is needed to better refine current systems and develop improved prognostic parameters in children to assist pediatricians in predicting which children are at risk for more severe courses of pancreatitis.

Chronic pancreatitis presents additional challenges to the pediatrician. In the adult population, several treatment options have been proposed, including exogenous pancreatic enzyme supplementation and antioxidant use. Patients with chronic pancreatitis often progress to develop pancreatic exocrine insufficiency, and a growing body of literature suggests that appropriate supplementation of exogenous pancreatic enzymes, although not curative, can assist in achieving symptomatic relief, prevent morbidity and mortality, and improve quality of life. Additionally, oxidative stress has been proposed as a mechanism leading to pancreatic gland destruction in chronic pancreatitis. Antioxidant agents such as selenium are decreased in patients with chronic pancreatitis, and additional research will need to focus on the benefits of antioxidant supplementation as a potential treatment option.

Ultimately, the underlying cause is an important piece of the medical investigation. Although immediate treatments are often similarly focused (eg, pain control, fluid management, gland rest), identifying the causal etiology assists in future therapeutic modalities after the stabilization of the presenting symptoms is achieved.

Finally, because pain control is often a cornerstone of management in pancreatitis, it is critical that physicians recognize patients who exhibit drug-seeking tendencies and address any abusive behaviors, or refer to a specialist who may have more experience in dealing with chronic pain.

## ONGOING CARE

### Follow-up

Children presenting with pancreatitis require follow-up in both the primary and specialty care settings. Given the relative rarity of the disease in children, it is imperative that close monitoring occurs after discharge from the hospital. In most cases, discharge criteria will not necessarily include complete resolution of the presenting symptoms or pancreatic enzyme elevations. In such cases, children should be reassessed for a return to baseline function and activity in the outpatient setting. As previously mentioned, pancreatic enzyme elevations may last for days after an acute pancreatitis attack, and although no universal guidelines direct follow-up care, obtaining repeat labs to confirm continued decreases in amylase and lipase levels may reassure families and physicians that the disease is indeed resolving. In some cases, such as those children whose clinical course was more complicated with documented pancreatic fluid collections (pseudocyst), repeat imaging may be indicated to assess for resolution. Because no specific guidelines have been developed to direct follow-up management, type and frequency of imaging as well as testing should be considered in consultation with a pediatric gastroenterologist. Genetic testing is an emerging modality available to pediatricians to further assess the initial etiologic insult as well as predict potential future episodes of pancreatitis. Because most cases of pancreatitis in children are single events, indications for genetic testing should be based on individual patient factors such as recurrent attacks of pancreatitis

or a strong family history. Again, consultation with a specialist may assist the primary pediatrician in discerning what, if any, tests may be indicated.

Children with chronic pancreatitis or extremely severe acute attacks with pancreatic necrosis may require additional monitoring for development of pancreatic endocrine and exocrine insufficiency. In the chronic setting, repeated episodes of inflammation ultimately result in irreversible gland damage, whereas similar damage can be caused by necrotic changes after an acute attack. Evidence of fat malabsorption or insulin insufficiency may be signs of pancreatic gland dysfunction and prompt additional investigations or treatments.

### Complications

Pancreatitis is associated with several known complications, including anatomic changes to the pancreatic tissue, gastrointestinal and metabolic dysfunction, and systemic complications (see Box 306-3).

Pseudocyst development has been recognized as one of the more common complications of pancreatitis in children, with formation occurring in up to 25% of cases, especially those whose underlying etiology is traumatic. With improved imaging, small pseudocysts are increasingly identified. Most resolve spontaneously, but those that persist and develop a mature capsule must be drained either endoscopically, surgically, or percutaneously with radiographic guidance.

Particular concern should be paid to the relationship between those patients with known hereditary pancreatitis and the development of pancreatic carcinoma. Patients with hereditary pancreatitis have a high risk for developing pancreatic cancer up to several decades after the initial onset of the pancreatitis. Hence, patient counseling and concomitant monitoring are crucial for appropriate management.

In the end, physician awareness of appreciated complications is important in the ultimate recognition and treatment of an individual patient's clinical course.

### Prognosis

In most cases, acute pancreatitis in children is a single event with a relatively predictable course and overall benign outcome. However, severe pancreatitis can have detrimental effects with long-term complications. This wide array of clinical progression is evident in the literature, with morbidity rates ranging from 0% to almost 80%, depending on study size and specific populations assessed. As noted above, prognostic scoring systems have been used in adults for some time and have dramatically improved the management of patients presenting with attacks of pancreatitis. Although such a scoring system has yet to gain complete validation in the pediatric population, increased research continues to contribute to the ability to predict which patients have a greater likelihood of developing severe pancreatitis with its associated complications. Such predictive capabilities would greatly improve the overall management of children with pancreatitis.

Children with chronic pancreatitis are a challenging and emerging population for physicians because ultimate prognosis depends on multiple factors,

**BOX 306-3 Complications of Pancreatitis****PANCREATIC**

- Ascites
- Diabetes mellitus
- Exocrine insufficiency
- Necrotizing pancreatitis
- Pancreatic abscess

- Sepsis
- Sudden death
- Thrombosis

including underlying cause, early recognition of increased susceptibility, family and patient education and understanding, and avoidance of exacerbating factors that contribute to recurrent attacks.

**Prevention**

Preventing acute pancreatitis in most cases is difficult because the cause is often unknown. After idiopathic causes, traumatic injury is the leading causes of acute pancreatitis in children. In the acute setting, improved childhood safety measures such as booster seats in cars may help prevent cases of acute pancreatitis. However, other common causes, such as systemic infection and structural abnormalities, are more difficult to prevent. It is therefore important for the pediatrician to maintain a broad differential in children so as not to delay appropriate treatment in a child with pancreatitis.

Preventive measures are increasingly important for patients with chronic pancreatitis. Understanding an individual's exacerbating factors is imperative. However, in children and adolescents with known chronic pancreatitis, universal preventive measures such as avoiding fatty foods, stress, alcohol, and tobacco may assist in decreasing future events and slow the irreversible damage of the pancreatic gland.

**WHEN TO ADMIT**

- All children with suspected acute pancreatitis warrant admission with initiation of supportive therapy and monitoring.
- Younger, smaller children with elevated white blood cell counts or LDH may benefit from direct ICU admission and intensive monitoring.
- Children with chronic pancreatitis present additional challenges and should be admitted based on the severity of the clinical symptoms (ie, intractable vomiting, need for intravenous fluids or nutritional support, inability to tolerate PO pain medications).

**WHEN TO REFER**

- Despite increasing prevalence, pancreatitis is still a relatively uncommon diagnosis in children. All patients diagnosed with pancreatitis would likely benefit from an evaluation by a pediatric gastroenterology specialist.
- More severe cases of pancreatitis with an associated hemorrhagic or necrotic component require surgical consultation for therapeutic peritoneal lavage or pancreatic necrosectomy.

- Patients with pancreatitis and intractable pain may benefit from evaluation by a pain specialist with more experience in dealing with chronic pain disorders.
- Patients with recurrent pancreatitis and a positive family history may benefit from a genetic evaluation by a specialist to determine the utility of additional genetic testing.

## Chapter 307

## PAPULOSQUAMOUS DISEASES

Jane Sanders Bellet, MD

A number of papulosquamous diseases occur in children. The hallmark of these diseases is the presence of scaly, raised lesions that range in size from small papules (1–3 mm in diameter) to large plaques (>10 cm in diameter). The scale can vary from thin desquamation to thick adherence. Seborrheic dermatitis is included in this category of disease but is described in detail in Chapter 326, Seborrheic Dermatitis.

### PSORIASIS

#### Etiology and Epidemiology

Psoriasis is a chronic inflammatory disease whose cause is a complex interplay of genetic and environmental factors. A number of psoriasis susceptibility loci have been mapped, and the HLA-Cw6 allele in particular is highly associated with the disease. Environmental factors such as streptococcal infection, physical stress, and psychologic stress can precipitate the onset of the

disease. A population-based study found that the annual incidence of psoriasis was approximately 40 per 100,000 individuals younger than 18 years.

#### Clinical Features and Diagnosis

Plaque psoriasis is the most common form of psoriasis in children. The classic lesion is a sharply demarcated, erythematous plaque with overlying silvery scale. The plaques are usually symmetric and occur commonly on the elbows and knees, but may also occur on the scalp, ears, gluteal cleft, and umbilicus. Removal of the scale can produce pinpoint bleeding (Auspitz sign), which is characteristic of psoriasis. Inverse psoriasis affects the intertriginous areas such as the axillae and groin (Figure 307-1) and appears as smooth, erythematous patches, usually without any scale. Small, drop-like papules with a silvery scale, called *guttate psoriasis* (Figure 307-2), commonly occur on the trunk and proximal extremities. Though pustular psoriasis (Figure 307-3) is rare in childhood, it can be seen during the first week of life. It can become generalized with hundreds to thousands of pustules occurring in areas of erythema and scaling, but it may remain localized to only the palms and soles, or in the folds of the neck and inguinal creases. Widespread erythema

**Figure 307-1** Plaque psoriasis on lower abdomen and thigh. Inverse psoriasis with lack of scale in the inguinal region.

**Figure 307-2** Guttate psoriasis triggered by group A streptococcal pharyngitis.

and exfoliation characterize erythrodermic psoriasis. Nail changes are helpful in diagnosis and include pitting (tiny pits on the nail surface), oil spots (yellowish-brown spots signifying separation of the nail from the nail bed), onycholysis (distal separation of the nail from the nail bed), and sometimes destruction of the entire nail. Psoriatic plaques in a linear fashion in areas of skin trauma (Koebner phenomenon) can be useful in diagnosis. Streptococcal disease often triggers the guttate form of the disease. Viral infection, sunburn, and drug eruptions also can precipitate the onset of psoriasis. Arthritis may also occur and can precede or follow the development of skin lesions. The most commonly involved joints are the knee and the small joints of the hands and feet. The diagnosis of psoriasis is usually clinical; however, a skin biopsy can be confirmatory.

### Management

Though no cure for psoriasis exists, effective treatment is available to control the disorder. The natural history of psoriasis includes remissions and exacerbations. The use of medium-potency topical corticosteroids with or without topical vitamin D (calcipotriene) can often control the condition. If new lesions develop with this regimen, high- or super-potency topical corticosteroids may be necessary. Coal tar preparations may be effective, but many patients do not like to use them because of cosmetic issues, including staining of clothes and tar odor. Other treatment modalities include UVB phototherapy, methotrexate, and biologic agents such as etanercept (tumor necrosis factor alpha inhibitor) and ustekinumab (interleukin-12 and interleukin-23 antagonist). Etanercept can be effective in the treatment of moderate to severe plaque psoriasis in children and adolescents. A recent study demonstrated that ustekinumab was more effective than etanercept in individuals 18 and older with moderate to severe plaque psoriasis. A phase 3 trial in adolescents aged 12 to 18 recently concluded. Oral retinoids can be effective in the treatment of generalized pustular psoriasis and erythroderma. Systemic corticosteroids should be avoided in the treatment of psoriasis because they can exacerbate the disease and can cause erythroderma following discontinuation.

**Figure 307-3** Pustular psoriasis with areas of erythema and many pustules.

## PITYRIASIS ROSEA

### Etiology and Epidemiology

The cause of pityriasis rosea is unknown. This common disorder usually occurs in children and adolescents, but infants also may be affected.

### Clinical Features and Diagnosis

In some children, pharyngitis, headache, and malaise may precede the appearance of the skin lesions, but this is not a usual occurrence. Classically, a single, oval, erythematous, scaly lesion (herald patch), usually greater than 1 cm in diameter, develops on the trunk, but may be seen anywhere on the body several days to weeks before the appearance of oval plaques with thin scale in a “Christmas tree” pattern orienting along skin cleavage lines (Figure 307-4). Atypical individual lesions can be vesicular, pustular, or purpuric. Mild pruritus may occur with the generalized eruption, which usually resolves within 4 to 8 weeks, but can take up to 6 months. Recurrences are uncommon. The diagnosis is usually clinical, but a skin biopsy can be confirmatory.

### Management

This is a self-limited disorder and most children do not require any treatment. Pruritus can be managed with emollients or oral antihistamines. Sunlight or UVB phototherapy can hasten the resolution of the lesions. In one study, oral erythromycin was effective in the treatment of pityriasis rosea.

**Figure 307-4** Oval, hyperpigmented plaques following skin cleavage lines in pityriasis rosea.

**Figure 307-5** Hyperpigmented, oval scaly, thin plaques in pityriasis lichenoides chronica.

## PITYRIASIS LICHENOIDES

### Etiology and Epidemiology

Though the cause of this uncommon disorder is unknown, 2 forms have been described: the acute form (pityriasis lichenoides et varioliformis acuta [PLEVA]) and the chronic form (pityriasis lichenoides chronica [PLC]). The usual onset is between 5 and 15 years of age.

### Clinical Features and Diagnosis

The characteristic PLEVA lesions are recurrent crops of erythematous papules and papulovesicles 2 to 4 mm in diameter that often become pustular, hemorrhagic, or necrotic. They occur most commonly on the trunk and extremities and usually spare the scalp, face, palms, and soles. Gradual resolution takes place over weeks to months. Postinflammatory hypopigmentation can occur, especially in darker-skinned children. A rare variant of PLEVA is the ulceronecrotic form in which patients have fever and ulceronecrotic plaques. These children can have extensive painful necrosis of the skin with subsequent secondary infection leading to septicemia.

In PLC, the characteristic lesions are reddish-brown, oval, scaly papules and small, thin plaques that usually occur on the trunk and extremities (Figure 307-5). The lesions may persist for months to several years before resolving without scarring. The diagnosis of PLEVA and PLC is sometimes difficult to make clinically and a skin biopsy can be confirmatory.

### Management

The lesions may resolve without treatment; however, emollients, oral antihistamines, and topical corticosteroids may be used to alleviate pruritus. Oral erythromycin or UVB phototherapy seem to hasten resolution of the lesions. Methotrexate and systemic corticosteroids are often used in cases of the febrile ulceronecrotic form.

## PITYRIASIS RUBRA PILARIS

### Etiology and Epidemiology

The cause of pityriasis rubra pilaris, an uncommon disorder, is unknown. Though most cases are sporadic, some may be familial.

**Figure 307-6** Keratoderma of the sole in pityriasis rubra pilaris.

### Clinical Features and Diagnosis

A combination of types of lesions characterizes this disorder and includes scaly, erythematous macules, reddish-orange keratotic papules, and yellow thickening of the palms and soles (keratoderma) (Figure 307-6).

A clinical classification of 5 types has been proposed: type I (classical type with adult onset) 55% of cases, type II (atypical type with adult onset) 5% of cases, type III (classical type with juvenile onset) 10% of cases, type IV (circumscribed type with juvenile onset) 25% of cases, and type V (atypical type with juvenile onset, usually hereditary) 5% of cases. A sixth, HIV-associated type has been proposed, but this is controversial. Types III and IV usually occur before puberty, while type V is usually present at birth or occurs in the first few years of life.

In type III, macules and papules coalesce into patches and plaques that spread from the head to the trunk and extremities over weeks to months. Unaffected skin or “islands of sparing” can be seen scattered within the erythrodermic skin. In type IV, the usual lesions are erythematous plaques on the elbows and knees. Follicular papules, scaly, widespread erythema as well as scleroderma-like bound-down skin of the palms and soles characterize type V. Keratoderma can occur in each of the types. A skin biopsy is helpful in diagnosis.

### Management

Spontaneous resolution of types III and IV may occur, but type V continues throughout life. With mild forms

**Figure 307-7** Shiny, flat-topped, violaceous, polygonal papules and plaques in lichen planus.

of types III and IV, emollients may relieve skin dryness, while keratolytics (lactic, salicylic, or glycolic acid-based products) may soften and decrease thickening of the skin.

Topical corticosteroids can help to relieve pruritus if present, and topical retinoids can help to smooth the papules, although this is not curative. Complete clearance of type IV PRP with topical tazarotene (retinoid) was recently reported. Oral retinoids are often used for severe type III and type V. A recent report demonstrated near-complete clearance with etanercept in a 16-year-old female with type V.

## LICHEN PLANUS

### Etiology and Epidemiology

Lichen planus is a disorder of unknown cause and is uncommon in children. Most cases are sporadic, although it can occur in families. The age of onset ranges from 1 year through adolescence.

### Clinical Features and Diagnosis

The characteristic lesions are shiny, flat-topped, violaceous, polygonal papules and plaques that vary in diameter from 2 to 15 mm (Figure 307-7). They usually occur in a symmetric fashion on the extremities, but they also may be seen on the scalp, face, genitalia, palms, and soles. Lesions on the buccal mucosa and tongue are less common, but appear as white, pinpoint papules in a lacy pattern (Wickham striae). Rare variations of lichen planus include bullous, linear, hypertrophic, and annular types. Nail involvement is rare in children, but may consist of longitudinal ridging or severe dystrophy. Lesions also may develop in a linear array at the site of skin trauma (Koebner phenomenon). Pruritus can be severe. The diagnosis is clinical; however, a skin biopsy can be obtained if the diagnosis is uncertain.

### Management

Treatment consists of medium- to high-potency topical corticosteroids, which help in the control of the pruritus and resolution of the lesions. Oral antihistamines also are effective in the relief of pruritus. Topical

**Figure 307-8** White, flat-topped papules in lichen nitidus.

corticosteroids in gel or solution form can be effective in relieving pain in oral erosions and ulcerations. Remission often occurs within 6 months. Some cases can take up to 2 years for resolution while oral involvement may take as long as 5 years to resolve. Systemic corticosteroids are useful in children with extensive or unresponsive lesions.

## LICHEN NITIDUS

### Etiology and Epidemiology

Lichen nitidus is a self-limited disorder of unknown cause that occurs primarily in preschool-aged and school-aged children. It is almost always sporadic, but several familial cases have been described.

### Clinical Features and Diagnosis

The characteristic lesions are flesh-colored to white, flat-topped papules 1 to 2 mm in diameter that can occur anywhere on the body, but are usually seen in clusters on the trunk (Figure 307-8). Pruritus may or may not occur. A useful diagnostic finding is the presence of a linear group of papules within an area of skin trauma (Koebner phenomenon). A skin biopsy is diagnostic but rarely necessary.

### Management

The lesions resolve spontaneously over months to years. Because many children are asymptomatic and the lesions resolve spontaneously, no treatment is necessary. Emollients, oral antihistamines, and topical corticosteroids may relieve pruritus.

## LICHEN STRIATUS

The characteristic lesions of lichen striatus are flesh-colored or erythematous papules 1 to 2 mm in diameter which can coalesce into a plaque. They occur most commonly on a single extremity in a linear distribution, following the lines of Blaschko (Figure 307-9), but also may be seen on the abdomen and face. If a lesion extends to a finger or toe, nail dystrophy may occur. The diagnosis is clinical and a skin

**Figure 307-9** Flesh-colored papules in a linear distribution in lichen striatus.

biopsy is rarely necessary. Because the lesions resolve spontaneously, they do not require treatment. Resolution may take months to years, but recurrences are rare.

## Chapter 308

## PARASITIC INFECTIONS

Nahed Abdel-Haq, MD; Pimpanada Chearskul, MD;  
Yaseen Rafee, MD; Basim I. Asmar, MD

### PROTOZOAL INFECTIONS

#### Amebiasis (*Entamoeba histolytica*)

##### Epidemiology

Amebiasis is caused by the protozoan *Entamoeba histolytica*, which also causes amebic liver abscesses and other rare extraintestinal diseases. Worldwide, approximately 40 to 50 million people develop colitis or extraintestinal disease annually, leading to 40,000 deaths. Although amebiasis is a worldwide disease, developing countries have significantly higher prevalence rates. The seroprevalance is as high as 50% in

certain developing areas. This is related to poor hygiene, inadequate water sanitation, and the use of human waste to fertilize crops.

In developed countries such as the United States, amebiasis is mainly seen in migrants from and travelers to endemic countries. Infection with pathogenic *E histolytica* is not a common cause of travelers' diarrhea. Gastrointestinal infection is uncommon in travelers who have spent less than 1 month in endemic areas.

Three species of entamoeba are found: the pathogenic *E histolytica* and 2 nonpathogenic entamoebaes, *Entamoeba dispar* and *Entamoeba moshkovskii*. Therefore, finding the cysts does not indicate invasive disease.

##### Life Cycle and Pathogenesis

*Entamoeba histolytica* has 2 forms: the cysts (the infective forms of the parasite) and the trophozoite. The cysts, when ingested along with contaminated food or drink, release 4 metacystic trophozoites. The ingested cysts, but not trophozoites, can survive the gastric barrier in normal humans. The trophozoites continue to divide via binary fission. The actively motile trophozoites lodge in the submucous layer of the cecum and rectosigmoid, their normal habitat. After a period, trophozoites transform into cysts that are passed in the stool. Trophozoites may be passed in the stool as well, but only the cysts are infective.

Under certain circumstances, the trophozoites invade the bowel wall, producing ulcers and causing destruction and tissue necrosis. The organism then gradually moves from the dead tissue toward healthy tissue. Extraintestinal disease may occur when trophozoites disseminate to other organs through the bloodstream.

##### Clinical Manifestations

All *E dispar* and *E moshkovskii* infections and 90% of *E histolytica* infections are asymptomatic. In general, intestinal amebiasis has a subacute onset, usually over 1 to 3 weeks. Symptoms range from mild diarrhea to severe dysentery, producing abdominal pain, diarrhea, and bloody stools. Nearly 50% of patients experience weight loss. Eight percent to 38% of patients may experience a fever. Fulminant colitis with bowel necrosis leading to perforation and peritonitis occurs rarely but is associated with a mortality rate of more than 40%. Ameboma (a nodular, tumorlike focus of proliferate inflammation in the wall of the colon), toxic megacolon, local perforation, peritonitis, and extraintestinal extension are other rare complications.

Amebic liver abscess is the most common extraintestinal manifestation of amebiasis. The infection occurs by trophozoites ascending the portal venous system. Amebic liver abscess (and other extraintestinal disease) is less common in children than adults. Most patients diagnosed with amebic liver abscess in the United States either will be from a country where amebiasis is endemic or will have a relevant travel history. Pain in the right upper quadrant, fever, anorexia, and fatigue are the symptoms of abscess formation. Concurrent diarrhea is present in less than one-third of patients, though some patients will have had dysentery in the previous few months. Jaundice is

uncommon. For travelers returning from an endemic area, presentation usually occurs within 8 to 20 weeks (median, 12 weeks). In 95% of patients, the presentation will be within 5 months of their return, though a longer lag (sometimes years) has been reported. Extension or rupture into the lung, pleural space, peritoneum, or pericardium may complicate the course of the amebic hepatic abscess.

### Diagnosis

Stool examination is less sensitive than antigen testing and it is considered a poor method for diagnosing intestinal amebiasis. For improved sensitivity, 3 fresh stool samples from separate days should be sent for analysis. However, microscopy cannot differentiate among *E histolytica* and *E dispar* or *E moshkovskii* strains. Other methods have been developed to differentiate among the species and to diagnose the invasive disease.

Serologic testing is useful to differentiate *E histolytica* infections from *E dispar* infections; *E histolytica* infection results in the development of antibodies, whereas *E dispar* infection does not. Because between 10% and 35% of uninfected individuals in endemic areas have antiamebic antibodies related to previous, often undiagnosed infection with *E histolytica*, a negative serology in these populations helps to exclude disease. However, a positive serology is not particularly helpful because it does not distinguish between acute infection and past exposure to the parasite.

In the endemic areas, Agar gel diffusion and counterimmunoprecipitation are more useful than indirect hemagglutination, because specimens usually become negative after 6 to 12 months. However, Agar gel diffusion and counterimmunoprecipitation are less sensitive than the indirect hemagglutination method.

Fecal and serum antigen detection assays have many advantages, including ease and rapidity of the tests, ability to differentiate among strains, greater sensitivity than microscopy, and potential for early diagnosis in the course of infection and in endemic areas where serology is less useful. Fecal antigen assays use monoclonal antibodies to bind to epitopes present on pathogenic *E histolytica* strains but not on nonpathogenic *E dispar* or *E moshkovskii* strains. These assays are now being used commercially to detect *E histolytica* infection using enzyme-linked immunosorbent assay (ELISA), radioimmunoassay, or immunofluorescence.

Diagnosing amebic infection and differentiating among the 3 strains can now be done by detecting parasitic DNA or RNA in feces via probes, but these methods currently are reserved as research tools. Polymerase chain reaction (PCR) techniques can detect *E histolytica* in stool specimens; these are the most sensitive and specific methods, but they are not widely available at present.

Liver amebic abscesses are usually diagnosed based on clinical presentation, recognition of epidemiologic risk factors, serology, and use of noninvasive imaging studies.

### Treatment

The goals of antibiotic therapy for intestinal amebiasis are both to eliminate the invading trophozoites and to prevent the asymptomatic carrier state of the

organism. The treatment for intestinal amebiasis or hepatic amebiasis is metronidazole (35–50 mg/kg/day divided in 3 doses orally for 10 days, maximum 750 mg 3 times daily). This should be followed by an intraluminal agent to target the cyst stage; this could be iodoquinol (30 mg/kg/day divided in 3 doses for 20 days), paromomycin (25–35 mg/kg/day in 3 divided doses for 7 days) or diloxanide furoate (20 mg/kg/day in 3 doses orally for 10 days).

Asymptomatic *E histolytica* infection should be treated with an intraluminal agent because of the potential risk of developing invasive disease and the risk of spread to household members; *E dispar* and *E moshkovskii* infections, however, do not require treatment.

### Amoebic Meningoencephalitis (*Naegleria fowleri*, *Entamoeba histolytica*, and Certain Species of *Acanthamoeba*, *Leptomyxa*, *Gephyramoeba*, and *Balamuthia*)

Knowledge that free-living amoebae are capable of causing human disease dates back to the 1960s. Before that, these amoebae were regarded as harmless soil organisms, or at most, commensals of mammals. Later, however, many amebic organisms were found to cause significant clinical disease in humans. These are *Naegleria*, *Acanthamoeba*, *Balamuthia*, and *Prototheca*.

These free-living amoebae cause 2 distinct clinical presentations: (1) an acute, fulminant disease known as primary amebic meningoencephalitis (PAM), which is caused by *Naegleria fowleri* in previously healthy children and young adults, or (2) granulomatous amoebic encephalitis (GAE) in immunocompromised patients caused by *Acanthamoeba* and *Balamuthia* species, which is usually chronic and slowly progressive.

*Entamoeba histolytica* causes central nervous system (CNS) abscesses that are distinct from CNS lesions caused by meningitis-causing free-living amoebae. Cerebral amebiasis results from hematogenous dissemination. Symptoms are usually of abrupt onset, and rapid progression to death occurs if treatment is delayed. Lesions may be seen on computed tomography (CT) scan as irregular foci without a capsule or surrounding enhancement. Treatment should be very prompt, and should include metronidazole and surgical intervention, if required for decompression.

### Epidemiology

Warm bodies of water such as man-made lakes and ponds, hot springs, and thermally polluted streams, rivers, and healing swimming pool waters are where *Naegleria* may be found. They are not found in seawater. The olfactory neuroepithelium and nasal passage are the ports of entry. Disease typically occurs in previously healthy children and young adults. Affected individuals characteristically have a recent history of water-sports activities in lakes, ponds, or inadequately chlorinated swimming pools. The organism has been isolated from nasal passages and throats of healthy individuals. It is unclear why disease occurs in only a small proportion of exposed individuals. *N fowleri* exists in the environment in 3 forms: trophozoite, which is the invasive form that penetrates the cribriform plate and invades the brain; resistant cyst; and transient flagellate.

Several species of *Acanthamoeba* can cause granulomatous meningoencephalitis disease in humans. *Acanthamoeba* species have a trophozoite and a resistant cyst stage but no flagellate stage, have been identified in soil, various water sources, air conditioners, contact lens fluid, and the noses and throats of healthy individuals. *Acanthamoeba* species are believed to gain access to the brain via the hematogenous route, after entering the human host through the respiratory tract or the skin, and then travel via circulation to the brain. Immunocompromised hosts develop a chronic infection (*Acanthamoeba* encephalitis), and immunocompetent hosts who wear contact lenses may develop *Acanthamoeba* keratitis if exposed to contaminated water.

### Clinical Manifestations

Patients with PAM present similarly to patients with fulminant bacterial meningitis and other meningoencephalitis. The incubation period is usually 2 to 15 days. After that, symptoms start as bifrontal headaches that do not respond to analgesics and fevers ranging from 38°C to 41°C. Alteration in taste or smell and/or rhinitis also may be noted early. Then patients develop emesis, seizures, and lethargy. Physical examination findings include nuchal rigidity, cerebellar ataxia, and dysfunction of the third, fourth, and sixth cranial nerves. Death usually occurs within 3 to 7 days after onset of initial signs and symptoms.

Granulomatous amoebic encephalitis is a disease of immunocompromised and debilitated individuals. These include patients with acquired immunodeficiency syndrome (AIDS), neoplasms, renal transplantation, and liver disease. As the name reflects, this infection is characterized by the host's granulomatous response to the presence of the amoeba. This typically is a chronic and insidious infection that can take weeks to years before it becomes clinically apparent. The symptoms include hemiparesis, personality changes, seizures, neck stiffness, headaches, and fever, and are the result of the single or multiple space-occupying intracranial lesions. In addition to GAE, *Acanthamoeba* is known to cause sinusitis, otitis media, cutaneous lesions, and corneal ulcers.

### Diagnosis

In general, infections caused by the free-living amoebae are difficult to diagnose, and most are recognized on autopsy or necropsy.

In PAM, neuroimaging studies may be normal early in the disease but may show signs of increased intracranial pressure later. Meningeal enhancement of the basilar region is frequently reported. Severe brain edema is a late finding that is indicative of poor outcome. Laboratory studies often reveal increased leukocyte count, hyperglycemia, and glycosuria. Cerebrospinal fluid (CSF) examination shows a pleocytosis with predominance of polymorphonuclear leukocytes, increased CSF protein, and normal or decreased glucose. Routine Gram stain and bacterial culture will be negative. The motile amoebae may be seen on a wet mount of the CSF, preferably unrefrigerated CSF collected within 30 minutes of the evaluation. Performing a culture on non-nutrient agar plated with *Escherichia coli* is a

definitive way to make the diagnosis. Because most cases are fatal, staining with hematoxylin-eosin (H&E) or immunofluorescence study of brain tissue is helpful in confirming a diagnosis of PAM, but this is usually done postmortem. There is little or no antibody response to the presence of the amoebae, because of the short duration of this fatal infection; serologic procedures, therefore, are of little or no help. Polymerase chain reaction (PCR) has been used to detect amoeba DNA in tissue and CSF samples, but the technique is still in its early developmental stages and requires more testing before its reliability can be certified.

In GAE, neuroimaging may reveal space-occupying lesions resembling abscesses, tumors, or hemorrhagic infarction. CSF examination reveals a picture similar to that of aseptic meningitis. Diagnosis is made by finding the amoebae in tissue sections stained with H&E or with indirect immunofluorescence using rabbit anti-amoeba serum samples. Cysts of infecting amoebae can be recognized in corneal scrapings that have been stained with Calcofluor white, a fluorescent stain that binds to polysaccharide polymers in the *Acanthamoeba* cyst wall. *Acanthamoeba* can also be identified by placing biopsy tissue in non-nutrient agar coated with a layer of bacteria. *Acanthamoeba* will emerge from tissue to ingest bacteria and can be identified on agar plates by microscopy.

### Treatment

The mainstay in therapy for PAM is intravenous, or sometimes intrathecal, amphotericin B. One survivor has been described who was treated with intravenous amphotericin, intrathecal amphotericin, oral rifampin, and intravenous and intrathecal miconazole. Even with combined therapy, survival has been the exception.

No optimal antimicrobial therapy exists for the encephalitis caused by *Acanthamoeba*. Multiple drugs have been used in both these infections with varying degrees of success, including amphotericin B, azithromycin, fluconazole, flucytosine, pentamidine isethionate, and sulfa drugs. In vitro, miltefosine and voriconazole are potentially useful drugs for the treatment of free-living amoebic infections, though sensitivities of the various genera, species, and strains differ.

Amoebic keratitis is treatable with 1 or more drugs. Chlorhexidine gluconate (a component of germicidal soaps) and polyhexamethylene biguanide (a disinfectant and swimming pool cleaner) have become the drugs of choice in treating keratitis.

Amoebic CNS infections should be treated at centers where neurologic, neurosurgical, and infectious disease experts are available. Consultation with the US Centers for Disease Control and Prevention (CDC) is advisable.

### Prevention

Natural or artificially warm waters, if they are not properly chlorinated, could harbor *Naegleria amoebae*. Effective chlorine levels are achievable in swimming pools and spas, but less so in the case of lakes and ponds. However, even chlorine levels between 0.5 and 1.5 parts per million are not protective all the time. In general, swimming in warm, stagnant, and possibly fecally contaminated waters should be avoided. Proper chlorination of swimming pools and avoiding diving and

direct introduction of water to the nostrils may help prevent infection. Following proper contact lens care procedures should protect wearers against infection.

### Cryptosporidiosis

*Cryptosporidium* is an intracellular coccidian protozoan parasite that causes gastrointestinal disease among humans as well as different animals including mammals, reptiles, and fish. The organism is 2 to 6  $\mu\text{m}$  in diameter. This protozoan has 10 named species. However, *Cryptosporidium parvum* is the main species that causes disease in humans. *C parvum* is further divided into 2 species: *C hominis* (previously *C parvum* genotype 1), which only infects humans, and *C parvum* (previously *C parvum* genotype 2), which infects both humans and animals.

*Cryptosporidium* is a common parasitic intestinal pathogen in humans. In recent years, it has been increasingly recognized as a cause of diarrhea in healthy individuals as well as severe gastrointestinal disease and life-threatening illness in patients with AIDS.

### Epidemiology

*Cryptosporidium* is seen both sporadically and in outbreaks of diarrheal illness worldwide. Cryptosporidiosis is particularly common in developing countries that have increased crowding and poor sanitation. Patients with underlying cellular and humoral immunodeficiencies are at increased risk for a prolonged and severe clinical course. These include patients with AIDS, organ transplantation, immunosuppressive drugs, immunoglobulin A (Ig) A deficiency and hypogammaglobulinemia.

Cryptosporidiosis is present in 1% to 3% of immunocompetent patients with diarrhea in developed countries compared with 7% to 10% in developing countries. The annual incidence is reported as 3.0 cases per 100,000 persons in the United States and 6.0 per 100,000 persons in Canada. The incidence is higher in children than adults. Reported seroprevalence rates are 25% to 60% in the United States and as high as 65% to 90% in developing countries.

*Cryptosporidium* is transmitted to humans via spread from an infected person (person-to-person contamination) or an infected animal. Because of the risk of autoinfection, ingestion of only 10 to 50 oocysts may cause infection. The infectious dose 50 in healthy persons is 132 oocysts. Extensive outbreaks of cryptosporidiosis have occurred in fecally contaminated environments such as municipal drinking water and swimming pools. The transmission and spread of cryptosporidiosis are facilitated by the resistance of the oocysts to disinfectants, the ineffective removal of oocysts by many filtration systems, and their ability to survive in the environment for months. The oocysts are resistant to chlorine and thus appropriately functioning filtration systems are critical to prevent spread. Most sand filters used in swimming pools are ineffective at oocyst removal. Several outbreaks of cryptosporidiosis have been reported including a large waterborne outbreak in Milwaukee, Wisconsin, in 1993. An estimated 403,000 people developed gastrointestinal symptoms after their drinking water became contaminated. Outbreaks of apple cider contamination with *Cryptosporidium* oocysts have also

been reported. An outbreak of cryptosporidiosis involving 350 people in Illinois at a contaminated waterpark was reported in 2001. Outbreaks involving consumption of contaminated food are less frequent than waterborne outbreaks.

Person-to-person transmission of *Cryptosporidium* can also cause outbreaks at day care centers; rates of 30% to 60% have been reported. Transmission is also common among household members, homosexuals, and health care workers. *Cryptosporidium* can also cause traveler's diarrhea because of contaminated drinking and swimming water. The incubation period for cryptosporidiosis is 2 to 14 days (median, 7 days). Oocyst excretion may continue for 1 week after resolution of symptoms in 73% of infected patients.

### Pathogenesis and Life Cycle

The complete life cycle of *cryptosporidium* requires only 1 host. Humans acquire the infection by ingesting thick-walled oocysts. The oocyst sporulates in the host and is infective immediately after excretion in the stools. Excystation in the gastrointestinal tract occurs in the upper small intestine via the action of proteolytic enzymes and bile salts and causes the release of 4 infectious sporozoites that invade the epithelial cells. The first intracellular stage is the trophozoite, which subsequently undergoes 3 nuclear divisions to form a group of 8 merozoites, which become the first-generation schizont. The merozoites released from the schizont invade other epithelial cells, forming the second-generation schizont composed of only 4 merozoites. The second-generation merozoites invade other epithelial cells and enter the sexual stage, forming microgametocytes and macrogametocytes. Each microgametocyte produces 12 to 16 microgametocytes, whereas each macrogametocyte transforms into 1 macrogametocyte. The 2 sexual stages combine to form the zygote, which later develops into an oocyst, thus completing the life cycle. Oocysts exist in 2 forms: thin- and thick-walled. Thin-walled oocysts sporulate and cause infection in the same person (autoinfection), whereas thick-walled oocysts are excreted in feces and infect new hosts. The infection is generally limited to the superficial parts of the small intestine, but in immunocompromised patients, the infection may spread to involve the biliary tree and pancreas or may disseminate to extraintestinal sites, mainly the respiratory tract.

The mechanism by which *Cryptosporidium* causes diarrhea is not well understood. *Cryptosporidium* causes secretory diarrhea that is associated with malabsorption. No specific toxin associated with *Cryptosporidium* has been identified yet. However, increased proinflammatory cytokine release has been demonstrated during the course of infection. The pathogenesis is probably multifactorial. Loss of vacuolated villous tip epithelium causes a reduction in the absorption area. Reduced lactase activity may cause lactose intolerance and malabsorption. Accumulation of abnormal metabolites in the intestinal lumen may stimulate bacterial overgrowth.

In addition, the host immune response to the infection, both cellular and humoral, may contribute to the inflammatory changes in the gastrointestinal tract.

The T-lymphocyte immune responses are essential to control the infection. Although specific immunoglobulins A, G, and M are produced during the course of illness, they are not associated with clearance of infection, especially in patients with immunodeficiency virus (HIV) infection. However, the production of interferon- $\gamma$  seems to be involved in the clearance of infection.

### Clinical Manifestations

Cryptosporidiosis varies from an asymptomatic infection to severe enteritis and dehydration leading to death. In children, up to 30% of infections may be asymptomatic. The most common manifestation of cryptosporidiosis is acute diarrhea characterized by frequent, watery, foul-smelling nonbloody stools. Diarrhea is commonly associated with malaise, nausea, anorexia, fatigue, abdominal cramps, and weight loss. Fever and vomiting are commonly seen in children who may be misdiagnosed as having viral gastroenteritis. In immunocompetent individuals, including healthy children, the diarrhea is self-limited and resolves spontaneously in 1 to 20 days (mean, 10 days). In the Milwaukee outbreak, the mean maximum number of stools was 19 per day (range, 1–90/d). Thirty percent of affected patients had a recurrence of diarrhea after a 2-day symptom-free period. Occasionally, healthy infants with cryptosporidiosis may develop chronic and persistent diarrhea leading to malnutrition and growth retardation.

In immunocompromised patients, particularly those infected with HIV, cryptosporidiosis frequently takes a severe and protracted course and can lead to significant malnutrition, wasting, dehydration, and death. The disease is particularly severe in those with CD4 counts less than 180/ $\mu$ L. Other clinical manifestations of cryptosporidiosis in patients with AIDS include cholecystitis, cholangitis, hepatitis, pancreatitis, and respiratory tract involvement. The biliary tract is affected in 10% to 30% of HIV-infected patients, and can lead to sclerosing or acalculous cholangitis. Biliary cryptosporidiosis is exclusively seen in patients with AIDS. Symptoms include right upper quadrant pain, fever, nausea, and vomiting with or without diarrhea. Serum alkaline phosphatase and  $\gamma$ -glutamyl transpeptidase are elevated. Radiologic investigations may show dilated intra- and extrahepatic bile ducts as well as a dilated, thick-walled gallbladder. Rarely, pancreatitis may result from involvement of the pancreatic duct.

Respiratory cryptosporidiosis is seen mainly in patients with AIDS. It is not clear if *Cryptosporidium* is a true pathogen or merely colonizes the respiratory tract, because it frequently coexists with other pathogens such as cytomegalovirus, *Mycobacterium* species, and *Pneumocystis jiroveci*. Clinical symptoms include cough, dyspnea, fever, expectoration, and chest pain.

### Diagnosis

Diagnosis of cryptosporidiosis depends on microscopic identification of the oocysts in stool, aspirated fluid, or tissue samples. Routine laboratory examination of stool samples for ova and parasites will not detect *Cryptosporidium*. Thus, the laboratory should be alerted to the potential diagnosis of cryptosporidiosis

to perform specific staining of the samples. Direct fluorescent antibody testing to detect oocysts in stools is considered the best diagnostic test by many laboratories because it provides the highest sensitivity and specificity. A combined direct fluorescent antibody test to detect *Cryptosporidium* oocysts and *Giardia* cysts in stools is available. A modified Kenyon acid-fast stain is used to identify *Cryptosporidium*. The stool samples are usually concentrated using either the sucrose flotation or formalin acetate methods before staining. The oocysts of *Cryptosporidium* are small (4–6  $\mu$ m) and can be missed without careful scanning of slides. At least 3 stool samples should be tested before considering a negative result. Enzyme-linked immunosorbent assay (ELISA) and immunofluorescent staining using monoclonal antibodies can be used to detect oocysts in stool and tissue specimens. Commercial ELISA kits that detect *Cryptosporidium* and *Giardia* antigens in stools are also available.

Serologic testing is available; however, testing is only useful for epidemiologic studies. PCR testing can be performed on stool samples and has been shown to be more sensitive than immunofluorescent and acid-fast staining. PCR is not commercially available but is particularly useful in detecting common source outbreaks by differentiating different *Cryptosporidium* genotypes.

### Treatment

Recovery from cryptosporidiosis depends to a large extent on the immune status of the host. In immunocompetent patients, cryptosporidiosis is a self-limited disease and supportive care, including hydration and nutritional support, may be adequate. Antimicrobial therapy is indicated in patients with severe infection and in immunocompromised hosts. The US Food and Drug Administration (FDA) has approved a 3-day course of nitazoxanide, a nitrothiazole benzamide, for treatment of children of age 1 year and older as well as adults with diarrhea caused by cryptosporidiosis or giardiasis. Paromomycin, a nonabsorbable aminoglycoside, used with or without azithromycin has been used in HIV-infected patients with cryptosporidiosis, but reliable efficacy data are lacking. The most important aspect of cryptosporidiosis treatment in HIV-infected patients is immune reconstitution using highly active antiretroviral therapy. Immune therapy such as oral human immune globulin, hyperimmune bovine colostrum, and bovine transfer factor has demonstrated some benefit.

Diarrhea in cryptosporidiosis is copious and attention to fluid and electrolyte management of affected patients is essential. Chronic diarrhea is frequently associated with malnutrition. Nutritional supplements containing medium-chain triglycerides may be helpful. Because chronic diarrhea may be associated with lactase deficiency in patients with cryptosporidiosis, milk and dairy products should be avoided. Total parenteral nutrition may be needed in HIV-infected patients with chronic diarrhea and weight loss.

### Prevention

The most important preventive measures are good hygiene practices, such as hand washing and appropriate

disposal of infected material. Using an appropriate water filter is another important measure to prevent or control an outbreak. Contact precautions are recommended for diapered and incontinent children. People with cryptosporidiosis should not use public recreational water when they have diarrhea and for at least 2 weeks after symptoms resolve. Although not universally recommended for immunocompromised patients, boiling drinking water for 1 minute is the most reliable method of killing *Cryptosporidium*, particularly in countries with unsafe drinking water. Alternatively, filtration devices that have a particle size rating of 1 to 5  $\mu\text{m}$  are effective in removing *Cryptosporidium* species.

### Toxoplasmosis (*Toxoplasma gondii*)

*Toxoplasma gondii* is an obligate intracellular coccidian parasite that belongs to the class Sporozoa. *Toxoplasma* infects several animal species as well as humans. Members of the cat family are considered definite hosts, whereas humans and mammals are considered intermediate hosts.

#### Epidemiology

*Toxoplasma* infections are distributed worldwide. The highest incidence of infection is in countries in which consumption of raw meat by people is common, such as France, the United States, and other Western countries. Infections are also common in regions with warm, humid climates including tropical areas. The presence of the domestic cat is an important risk factor associated with disease transmission in different parts of the world.

Humans acquire infection by ingesting cysts that are present in raw or undercooked meat or oocysts in material contaminated by cat feces.

Disease outbreaks have occurred following contamination of drinking water supplies. Infection may follow blood transfusion. It may also follow stem cell or solid organ transplantation. Congenital infection is seen after the acquisition of a primary maternal infection during pregnancy. Newborns are most frequently infected when maternal infection is acquired in the third trimester. However, the clinical manifestations of congenital toxoplasmosis are most severe in cases of first-trimester maternal infection during organ development.

#### Life Cycle and Pathogenesis

Cats acquire infection by eating rodents or uncooked kitchen meat that contains *Toxoplasma* cysts. The sexual phase takes place in the intestinal epithelial cells of cats. This is followed by appearance of oocysts in the feces in 3 to 18 days. Shedding of oocysts may persist for approximately 2 to 3 weeks. Shedding is more likely to occur in kittens than older cats. First infection in a cat is associated with shedding of millions of oocysts per day. The oocyst becomes infectious in 1 to 3 days after it sporulates.

The asexual phase occurs in the intermediate hosts, including humans and mammals. Following ingestion, the sporozoites are released in the intestine and become free trophozoites. From there, trophozoites are taken up by macrophages and transported via the

bloodstream to different organs. The most commonly involved organs are the skeletal muscles, brain, cardiac muscle, lymph nodes, eyes, and lungs. They proliferate by budding, and form clusters consisting of vacuoles of macrophages called *pseudocysts*. Because of their rapid proliferation and invasion, they are called *tachyzoites*. After the host immune response becomes established, as occurs in immunocompetent patients, the cysts are formed. The wall of the cyst will form and the organisms within the organisms are no longer actively multiplying. The organisms in these cysts are thus called *bradyzoites*. Morphologically, the tachyzoites and bradyzoites are similar except for the rate of proliferation. Both measure 2 to 6  $\mu\text{m}$ .

Infection in immunocompetent patients is limited and cellular necrosis is controlled. The incubation period is 4 to 21 days. Both cellular and humoral immune responses to *Toxoplasma* develop. However, not all organisms are killed, and cysts may remain in any organ without causing any symptoms or significant damage. Under certain conditions, such as immune dysfunction, or in patients with HIV infection, multiplication of organisms causes the cysts to rupture and release bradyzoites. An inflammatory response is seen, which is characterized by infiltration of lymphocytes, monocytes, and plasma cells and formation of granulomas. This may lead to significant dysfunction in affected organs especially the brain and the eye. It may also lead to disseminated toxoplasmosis.

#### Clinical Manifestations

**CONGENITAL DISEASE.** Congenital toxoplasmosis typically follows a primary infection in the mother during pregnancy. Rarely, the fetus may be infected after *Toxoplasma* is reactivated in immunocompromised mothers, including those with HIV infection. The risk of transmission of *Toxoplasma* infection to the fetus is 15% to 20% if the mother is infected in the first trimester but rises to 60% to 65% if the mother becomes infected in the third trimester. The incidence of congenital toxoplasmosis in the United States is 1 in 1,000 live births. Severely affected fetuses may result in still birth, abortion, or early neonatal death. However, 70% to 90% of congenitally infected infants are asymptomatic. If untreated, a large proportion of asymptomatic infants may develop late-onset sequelae such as choreoretinitis, learning disabilities, and mental retardation months to years later. Clinical manifestations of congenital toxoplasmosis at birth can include hepatosplenomegaly, lymphadenopathy, hydrocephalus, or microcephaly. Clinical signs of meningoencephalitis such as seizures and neurologic deficits may also be present. Other manifestations include choreoretinitis, rash, jaundice, thrombocytopenia, and anemia. Radiologic studies such as ultrasound or computed tomography may show calcifications or dilated ventricles. The calcifications in toxoplasmosis are scattered throughout the brain in contrast to the periventricular calcifications of cytomegalovirus infection.

**ACQUIRED DISEASE.** Most *Toxoplasma* infections acquired after birth are asymptomatic. In symptomatic patients, the most frequent clinical manifestation is cervical lymphadenopathy. Concomitant nonspecific signs and symptoms such as fever, myalgia, and fatigue

may be present. The lymphadenopathy may less frequently present in other regions or may be generalized. In some patients, infectious mononucleosislike manifestations such as sore throat, fever, malaise, adenopathy, splenomegaly, rash, and atypical lymphocytes may be present. Rare complications of primary infection include hepatitis, pneumonitis, myocarditis, pericarditis, and encephalitis.

**DISEASE IN IMMUNODEFICIENT PATIENTS.** Disease in immunocompromised patients including those infected with HIV is more severe than infection in a normal host. Disseminated toxoplasmosis and death may occur. More frequently, these patients develop localized infections in different organs including encephalitis, meningoencephalitis, pneumonitis, myocarditis, pericarditis, and hepatitis. Encephalitis in patients with AIDS usually follows reactivation of chronic disease especially in those with CD4 cell counts less than 100/mL. *Toxoplasma* is the most frequent cause of focal brain lesions in patients with AIDS. Brain involvement can be localized or diffuse. Patients present with fever, headache, deterioration in mental status, seizures, and focal neurologic deficits. Hemiparesis and abnormal speech are the most typical focal findings. Computed tomography scans typically show brain abscesses or ring-enhancing lesions. *Toxoplasma* pneumonitis in patients with AIDS may mimic *P. jiroveci* pneumonia.

**OCULAR DISEASE.** *Toxoplasma* is the most common recognized cause of choreoretinitis in the United States. Isolated ocular toxoplasmosis most frequently follows congenital infection but rarely may follow an acquired infection. Choreoretinitis is bilateral in the congenital form and unilateral in the acquired form of toxoplasmosis. Most affected patients are young adults. Choreoretinitis is not usually the sole manifestation of acquired toxoplasmosis. Nystagmus is a common manifestation of congenital ocular toxoplasmosis. Acute choreoretinitis is characterized by blurred vision, photophobia, and central vision loss secondary to involvement of the macula. Fundoscopy shows yellow-white cottonlike patches with indistinct borders. During the healing stage, black pigment will be seen at the margins. The lesions heal in few weeks to several months. Relapses are frequent and visual loss may occur. Other complications of congenital ocular involvement include choreoretinal scars, microphthalmia, cataract, and retinal detachment.

### Diagnosis

The most definite diagnostic test for toxoplasmosis is isolation of the organism from infected tissue or body fluids either by inoculating into laboratory animals or tissue culture. However, these techniques are not routinely available. Thus, the primary method currently used for diagnosis is based on the detection of specific antibodies and monitoring of the immune response. Recently, molecular methods have been developed, which use PCR for detecting *Toxoplasma* DNA in tissue and fluid samples. Clinical and laboratory data should be carefully correlated during patient evaluation and management.

The most commonly used serologic test is the ELISA. Serum IgG usually becomes positive 4 to

8 weeks after infection and remains positive indefinitely. Paired serum samples should be tested simultaneously 3 weeks apart to document at least a fourfold rise in antibody titers. Serum IgM levels should also be tested simultaneously with IgG. The ELISA IgM tests are more sensitive than the indirect immunofluorescence antibody test. The IgM test may remain positive for 6 months and false-positive results can occur. In newborns and pregnant women, the serum levels of IgA and IgE for *Toxoplasma* also can be tested. These tests become negative sooner than the IgM, thus giving more precise information about the timing of infection. However, anti-*Toxoplasma* IgA and IgE are only available at *Toxoplasma* referral laboratories (Palo Alto Medical Foundation Research Institute, Palo Alto, CA).

IgG avidity testing is used to predict the timing of *Toxoplasma* infection. The presence of these high-avidity antibodies reflects infection at least 3 to 5 months earlier. Testing of high-avidity antibodies is most useful in assessing the risk of transmission of *Toxoplasma* from the mother to the fetus or when only 1 sample is available at the time of decision making. Low-avidity antibodies are, however, unreliable in predicting a recent infection.

Pregnant women should ideally know their serologic status for *Toxoplasma* before conception. If positive, no further testing is needed. However, if the mother was found during pregnancy to have a positive *Toxoplasma* IgG antibody, the serum titers should be repeated for both IgM and IgG after 3 weeks to determine if she has a primary infection. A definitive diagnosis of congenital toxoplasmosis during pregnancy can be made via amniotic fluid sampling. Detecting *Toxoplasma* in amniotic fluid with DNA PCR, tissue culture, or mouse inoculation is considered diagnostic. Similarly, fetal blood sampling to isolate *Toxoplasma* from fetal white blood cells and to test for IgM antibody also may be used. Serial ultrasound examinations can be performed to assess brain ventricular size or other signs of infection.

After delivery, infants should be evaluated for congenital toxoplasmosis if the mother has a primary infection or if she has HIV infection and serology suggestive of past infection. If the diagnosis is suspected, the patient should have a complete clinical evaluation including ophthalmologic, neurologic, and auditory examination. Brain CT should be performed to rule out brain calcification or hydrocephalus. Serum samples should be evaluated for IgG, IgM, IgA, and IgE antibodies for *Toxoplasma*. CSF samples should be analyzed for cells, protein, glucose, *Toxoplasma* antibodies, and *Toxoplasma* PCR. Diagnosis is confirmed serologically by demonstrating a positive IgM or IgA, an IgG titer that is higher in the infant than in the mother, or a persistently positive IgG beyond 1 year of age.

The diagnosis of toxoplasmosis in older children and adults who are immunocompetent relies on the presence of a positive IgM titer or a fourfold rise in IgG titers after 3 weeks. Classic histopathologic findings in tissue samples such as lymph nodes strongly support the diagnosis. Histologic identification of proliferating organisms provides a definite diagnosis.

Similarly, culture-isolated *Toxoplasma* in tissue or body fluid samples or identification of nucleic acid material with DNA PCR is definitive.

In immunocompromised patients, including those with HIV infection, serologic testing may not be reliable. A fourfold rise in titer may not occur in these patients when they acquire a primary infection. Those who have an old infection are diagnosed on the basis of a positive IgG titer. The diagnosis of *Toxoplasma* encephalitis in patients with AIDS relies on characteristic clinical and radiologic findings. Patients with positive *Toxoplasma* IgG titers are treated presumptively. If no response to treatment is seen, identification of *Toxoplasma* in blood or CSF by means of DNA PCR testing may be needed.

Patients with ocular involvement are diagnosed on the basis of classic eye findings and serologic testing. Examination of the vitreous fluid or aqueous humor on DNA PCR may be needed if the retinal lesions are atypical or the patient fails to respond to antimicrobial therapy.

### Treatment

Treatment is not indicated in immunocompetent patients unless clinical symptoms are severe or complications occur. Immunocompromised patients, especially with acute HIV/AIDS infection, should be treated even if they are asymptomatic. Infected pregnant women and neonates, whether symptomatic or not, should also be treated as soon as the diagnosis is established. Patients with chorioretinitis are treated when symptoms are present or progressive.

The recommended treatment in most cases is the combination of pyrimethamine and sulfadiazine. These drugs act on the tachyzoites and the cysts forms are not affected. Thus, lifelong daily maintenance therapy is needed in patients with AIDS. The dose of pyrimethamine in children is 2 mg/kg per day for 3 days then 1 mg/kg per day to a maximum daily dose of 25 mg given for 4 weeks. The dose of sulfadiazine is 85 to 100 mg/kg per day divided every 6 hours for 3 to 6 weeks. Because pyrimethamine is a folic acid antagonist, supplemental leukovorin (folinic acid) is given to prevent bone marrow toxic effects. Pyrimethamine is not given to pregnant women, especially during the first trimester, because of its teratogenic effects. Instead, sulfadiazine alone or spiramycin can be used. However, pyrimethamine and sulfadiazine may be considered for treatment of infections acquired in the third trimester. Patients who are allergic to sulfa drugs can be given a combination of clindamycin and pyrimethamine.

For congenital toxoplasmosis, pyrimethamine and sulfadiazine (with folinic acid supplements) should be continued for a prolonged period, often for 1 year.

Corticosteroids are given in addition to pyrimethamine and sulfadiazine in patients with ocular toxoplasmosis and selected patients with CNS disease.

Prophylactic therapy for toxoplasmosis is given to children with HIV/AIDS with severe immunosuppression and positive *Toxoplasma* IgG antibodies. The drug of choice is trimethoprim-sulfamethoxazole. Alternative therapies are dapsone plus pyrimethamine (with supplemental folinic acid) or atovaquone.

Prophylaxis is also given to prevent recurrence of toxoplasmosis in immunosuppressed patients with prior *Toxoplasma* encephalitis. The recommended regimen is pyrimethamine plus sulfadiazine plus folinic acid. Alternatively, clindamycin plus pyrimethamine plus folinic acid or atovaquone may be used for those who cannot tolerate sulfa drugs.

### Prevention

Preventive measures are aimed at hygienic practices during cat contact and preventing raw meat and shellfish consumption. Pregnant women with negative or unknown serologic status for *Toxoplasma* as well as immunocompromised individuals should avoid contact with cats, cat litter, or soil that has been contaminated by cat feces. Hygienic practices such as using gloves and hand washing should be stressed in such settings. Deep freezing to  $-12^{\circ}\text{C}$  for 24 hours as well as cooking meat, particularly ham and lamb, to an internal temperature of  $65.5^{\circ}\text{C}$  to  $76.6^{\circ}\text{C}$  or until no longer pink will kill cysts. All fruits and vegetables should be washed thoroughly. Ingestion of untreated water, especially in developing countries, should be avoided. Cats may be prevented from acquiring infection by restricting their outdoor activities and feeding them commercially prepared cat food. Because the oocysts are not infective until at least 36 to 48 hours after passage, daily cleaning of cat litter boxes is a simple and effective control measure.

### Malaria (*Plasmodium falciparum*, *P vivax*, *P ovale*, *P malariae*)

#### Epidemiology

Malaria is a global problem and a leading cause of death and illness. The World Health Organization (WHO) report of 2005 estimated that between 350 and 500 million clinical episodes of malaria occur every year, resulting in at least 1 million deaths. Most of the cases and deaths are in sub-Saharan Africa, and most involve children younger than 5 years.

Four species of the plasmodia infect humans: *Plasmodium falciparum*, *P vivax*, *P ovale*, and *P malariae*. They are transmitted from person to person by the bite of the female *Anopheles* mosquito. *P falciparum* causes the most severe disease and it is the predominant malarial parasite in tropical Africa, Southeast Asia, and Oceania. *P vivax*, predominant in Southeast Asia, along with *P falciparum*, causes the most malaria infections worldwide. *P malariae*, the least common type, produces long-lasting infections. *P ovale* is uncommon and found largely in Africa.

#### Life Cycle

The malaria parasites have 2 different life cycles in 2 hosts, the female *anopheles* mosquito and the human. When certain forms of blood-stage parasites ("gametocytes") are picked up by a female *Anopheles* mosquito during a blood meal, they start the sexual stage of life inside the mosquito. This leads to the formation of infective-stage sporozoites which reside in the mosquito's salivary gland and can access the bloodstream of a human when the mosquito feeds again.

In humans, the parasites grow and multiply first in the liver cells (extraerythrocytic stage) and then in the red blood cells (the erythrocytic stage). In the blood, successive broods of parasites grow inside the red cells and destroy them, releasing daughter parasites (“merozoites”) that continue the cycle by invading other red cells. Thus, the mosquito carries the disease from 1 human to another (acting as a “vector”). In contrast to the human host, the mosquito vector does not suffer from the presence of the parasites.

### Pathogenesis

All the typical clinical symptoms and severe disease pathology associated with malaria are caused by the asexual erythrocytic or blood-stage parasites. When the parasite develops in the erythrocyte, numerous known and unknown waste substances such as hemozoin pigment and other toxic factors accumulate in the infected red blood cell. When the infected cells lyse and release invasive merozoites, these waste products are dumped into the bloodstream. The hemozoin and other toxic factors such as glucose phosphate isomerase stimulate macrophages and other cells to produce cytokines and other soluble factors that act to produce fever and rigors and probably influence other severe pathophysiology associated with malaria.

In *P falciparum* infections, consciousness can be impaired by various mechanisms interacting with each other. One of these mechanisms is obstruction of the cerebral microvascular flow by parasites, which induce sequestration of the infected and uninfected erythrocytes. Parasite binding is mediated by a group of variant surface antigens expressed at the red cell surface during development. The best described is *P falciparum* erythrocyte membrane protein-1, which is encoded by a family of approximately 60 variant genes associated with different binding phenotypes. Interleukin 6 and 10, nitric oxide, tumor necrosis factor, and various other inflammatory factors may play a role in the pathogenesis of cerebral malaria.

### Clinical Manifestations

The incubation period in most cases varies from 7 to 30 days. *P falciparum* most frequently is observed to have shorter periods, and *P malariae* has longer periods of incubation. Antimalarial prophylaxis taken by travelers can delay the onset of symptoms by weeks or months. The clinical presentation may also be affected by the malaria species. *P vivax* and *P ovale* are associated with hypnozoite or dormant-stage liver parasites. This liver stage of the disease is only associated with these 2 malaria species and can lead to a relapse months after the infective mosquito bite. Returned travelers should always remind their physicians of any travel in malaria-risk areas during the past 12 months.

Symptoms of malaria occur every second day with the “tertian” parasites (*P falciparum*, *P vivax*, and *P ovale*) and every third day with the “quartan” parasite (*P malariae*). However, these classic patterns are rarely observed; more commonly, the patient presents with a combination of the following symptoms that resemble a flulike illness: fever, chills, sweats, headaches, nausea and vomiting, body aches, and general malaise.

Anemia and an enlarged spleen may be seen on physical examination.

Severe malaria occurs when *P falciparum* infections are complicated by serious organ failures or abnormalities in the patient’s blood or metabolism. The manifestations of severe malaria that could be confused with severe bacterial sepsis include cerebral malaria, abnormal behavior, impaired consciousness, seizures, coma, or other neurologic abnormalities; severe anemia resulting from hemolysis, hemoglobinuria, pulmonary edema, or acute respiratory distress syndrome, which may occur even after the parasite counts have decreased in response to treatment; abnormalities in blood coagulation and thrombocytopenia; cardiovascular collapse; and shock.

Cerebral malaria, as proposed by the WHO, is a clinical syndrome characterized by coma at least 1 hour after termination of a seizure or correction of hypoglycemia, detection of asexual forms of *P falciparum* malaria parasites on peripheral blood smears, and exclusion of other causes of encephalopathy. The main neurologic features are coma, seizures, and brainstem signs. The mortality rate in adults and children is approximately 20%, and most deaths happen within 24 hours of admission, before antimalarial drugs may have had time to work. In African children, a high incidence of neurologic deficits (10.9%) was reported in studies that used similar definitions of cerebral malaria. Some deficits are transient (eg, ataxia), whereas others (eg, hemiparesis) improve over months but may not resolve completely.

Congenital malaria may be seen in infants of infected mothers. Symptoms include fever, severe anemia, and hepatosplenomegaly.

### Diagnosis

Prompt and accurate diagnosis of malaria is part of effective disease management. The most commonly used diagnostic tool is microscopic diagnosis, and more recently, rapid diagnostic tests based on immunochromatographic techniques. Microscopic examination remains the “gold standard” for laboratory confirmation of malaria. Both thick and thin smears are recommended. Thick smears are more sensitive but they cannot be used to differentiate among the different malaria species. Smears should be repeated every 12 to 24 hours for 72 hours if malaria is suspected and the initial smears are negative. Diagnosis of malaria can be difficult in the nonendemic areas because physicians are not familiar with the disease and laboratory technicians inexperienced with malaria may fail to detect parasites when examining blood smears under the microscope. On the other hand, in endemic areas, finding malarial parasites in an individual’s blood specimen could represent solely a carrier state, because these individuals develop enough immunity to protect them from the illness, not from the infection. Other diagnoses should not be overlooked when the parasites are found in such individuals’ blood specimens.

The quantitative buffy coat technique is useful for screening populations for malaria and for detecting asymptomatic carriers to control further transmission of the disease in the community. However, the

diagnosis has to be confirmed with peripheral smears. Serology, using either indirect immunofluorescence or ELISA, does not detect current infection but rather measures past experience, so it may be useful for epidemiologic surveys.

Other new tests include detection of the parasite nucleic acid with PCR, DNA probe, and rapid diagnostic tests using different methods, such as immunochromatography. PCR tests are more sensitive and specific than microscopy but are only available in reference laboratories including some state health departments. Although PCR is typically not readily available, it is very helpful in confirming the infecting species and detecting drug resistance mutations. A new rapid diagnostic test for antigen detection is available in the United States. However, the test cannot confirm the malaria species and may fail to detect low-density *P vivax* infections. In addition, false-positive and -negative test results have been reported with the rapid test and mixed infections may not be detected accurately. Thus, microscopic evaluation should always accompany rapid diagnostic tests to provide additional identification and to quantify the percentage of parasitemia.

### Treatment

**CHEMOTHERAPY.** Malaria must be recognized promptly to treat the patient in time and to prevent complications.

Malaria is a nationally notifiable disease and all cases should be reported to the state health department, which forwards them on to the CDC. Three main factors should be considered when treating malaria: the infecting *Plasmodium* species, the clinical status of the patient, and the drug susceptibility of the infecting parasites as determined by the geographic area in which the infection was acquired. For treatment of *P vivax* and *P ovale*, treatment needs to include drugs that target the liver to minimize the likelihood of recurrence. Patients should be checked for glucose-6-phosphate dehydrogenase deficiency before they are given primaquine. In general, if the diagnosis of malaria is suspected and cannot be confirmed, or if the diagnosis of malaria is confirmed but species determination is not possible, antimalarial treatment effective against *P falciparum* should be selected because all forms of malaria are susceptible to treatment of *P falciparum*. Detailed information about the treatment of malaria is available at the CDC Web site ([www.cdc.gov/malaria/diagnosis\\_treatment](http://www.cdc.gov/malaria/diagnosis_treatment)). The standard drug treatment for uncomplicated (not severe) malaria is summarized in Table 308-1. The treatment of severe malaria should be parenteral with continuous infusion of quinidine gluconate, until the patient can take oral medication and the parasite density is less than 1%. Therapy should be combined with doxycycline, tetracycline, or clindamycin. Patients with severe malaria or cerebral malaria should be monitored closely in the intensive care unit setting; side effects such as hypoglycemia should be monitored also. Consultation with the CDC for the treatment of such severe cases is recommended.

Artemisinin derivatives such as artemether and artesunate are used globally in combination regimens

to treat malaria and could be administered orally, parenterally, or rectally. Oral artemether/lumefantrine is active against chloroquine-resistant *P falciparum* and is approved by the FDA for treatment of acute uncomplicated malaria. Artemether is not approved to treat severe malaria or to prevent infection. Oral artesunate is not available in the United States and only the intravenous formulation is available through the CDC. Intravenous artesunate is typically reserved for patients with severe malaria who cannot tolerate or fail to respond to intravenous quinidine. When used, artesunate should be administered for a minimum of 3 days and given with an oral antimalarial agent such as atovaquone-proguanil, clindamycin, or mefloquine when the patient can tolerate oral intake. Artesunate followed up with mefloquine was associated with a cure rate of greater than 90%.

Finally, a self-treatment course of atovaquone-proguanil can be given to travelers who do not take an antimalarial drug for prophylaxis, are on a less-than-effective regimen, or may be in very remote areas, when they develop fever. Travelers should be advised that self-treatment is not considered a replacement for seeking prompt medical help.

**SUPPORTIVE TREATMENT.** Various supportive measures should be taken to optimize the treatment of patients. These include close monitoring of the fluid and electrolyte status of the patient, treating the convulsions with phenobarbital or diazepam, and vigilance about hypoglycemia, a common complication of severe malaria. Anemia should be corrected with packed red blood cell transfusions. The CDC recommends that exchange transfusion be considered for persons with a parasite density of greater than 10% or severe complications. Gram-negative sepsis must be suspected whenever patients present with shock; appropriate antibiotics should be started after blood cultures are obtained. No added benefits have been shown from using steroids, dextran, heparin, and osmotic diuretics.

### Prevention

Prevention of malaria is achieved through the following methods: preventing *infection* by reducing the population of the anopheles mosquitoes and avoiding bites by parasite-carrying mosquitoes (vector control), or preventing *disease* by using prophylactic antimalarial drugs.

Travelers from nonendemic countries should take precautions against acquiring malaria when they visit a malaria-risk area. These include chemoprophylaxis in addition to following measures to prevent contact with mosquitoes. Detailed guidelines about the chemoprophylaxis of malaria for travelers to endemic areas are available at the CDC Web site ([www.cdc.gov/travel](http://www.cdc.gov/travel)). Table 308-2 summarizes the recommended chemoprophylaxis for travelers. Chemoprophylaxis should begin 1 week before arrival in the area with endemic infection (except doxycycline and atovaquone-proguanil, which should be started 1 to 2 days before arrival), allowing time to develop blood concentrations of the drug and evaluate for adverse reactions. These medications should be continued for 1 week when receiving atovaquone-proguanil and 4 weeks when receiving the

**Table 308-1** Chemotherapy of Uncomplicated Malaria

DRUG	DOSAGE
<b>All <i>Plasmodium</i> species except chloroquine-resistant species<sup>a</sup></b>	
<b>Oral drug of choice:</b> Chloroquine Phosphate	10 mg base/kg (max 600 mg base), then 5 mg base/kg 6 hrs later, then 5 mg base/kg at 24 and 48 hrs
OR	
Hydroxychloroquine	10 mg base/kg (max 620 mg base), then 5 mg base/kg 6 hrs later, then 5 mg base/kg at 24 and 48 hrs
<b><i>P falciparum</i> acquired in areas of chloroquine resistance (if species is not known, assume chloroquine resistance)</b>	
<b>Oral drug of choice:</b> Atovaquone/Proguanil	<5 kg: not indicated 5–8 kg: 2 peds tabs once/day × 3d 9–10 kg: 3 peds tabs once/day × 3d 11–20 kg: 1 adult tab once/day × 3d 21–30 kg: 2 adult tabs once/day × 3d 31–40 kg: 3 adult tabs once/day × 3d >40 kg: 4 adult tabs once/day × 3d

DRUG	DOSAGE
<b>Parenteral drug of choice (severe infection): all <i>Plasmodium</i> species</b>	
Quinidine Gluconate	10 mg/kg loading dose (max 600 mg) in normal saline over 1–2 hrs, followed by continuous infusion of 0.02 mg/kg/min until PO Quinine Sulfate (30 g/kg/day in 3 doses × 7 days) therapy can be started
PLUS either	
Doxycycline	4.4 mg/kg/day in 2 doses × 7d, preferred PO if tolerated
OR	
Tetracycline	25 mg/kg/day in 4 doses × 7d
OR	
Clindamycin	20 mg/kg/day in 3 doses × 7d, preferred PO if tolerated
OR	
Artesunate (followed by one of the following oral agents: atovaquone/ proguanil, clindamycin or mefloquine)	2.4mg/kg/dose IV × 3 days at 0, 12, 24, 48 and 72 hrs (Investigational new drug, contact CDC for information on use)
<b>Prevention of relapses: <i>P vivax</i> and <i>P ovale</i> only</b>	
Primaquine Phosphate	0.6 mg base/kg × 14d

<sup>a</sup>Chloroquine resistant species include *P falciparum* acquired in most areas and *P vivax* acquired in New Guinea and Indonesia, see CDC for detailed map.  
<sup>b</sup>Artemether/lumefantrine tablet: 20mg artemether and 120mg lumefantrine. Take with food or whole milk.  
Modified in part from Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015.

other medications, after departure from the endemic areas. In endemic areas, chemoprophylaxis is used for selected high-risk groups, such as pregnant women and young children.

Vector control aims to decrease contacts between humans and vectors of human disease. Vector control for the prevention of malaria includes insecticide-treated bed nets, indoor residual spraying, and source reduction (larval control). Dichlorodiphenyltrichloroethane (DDT) meets most of the WHO criteria for indoor insecticide. However, resistance to DDT and dieldrin and concern over their environmental impact led to the introduction of other, more expensive insecticides, such as pyrethroids. Pyrethroids are safer to apply than most other insecticides, resistance to them is limited at present, and they are easier to store and transport. Source reduction (larval control) is the method of choice for mosquito control when the breeding sites of the mosquito species are easy to find and treat.

Insecticide-treated bed nets (ITNs) are now an important method for controlling malaria. However, to maintain their efficacy, these nets must be retreated at intervals of 6 to 12 months, more frequently if the nets are washed. House screening to prevent entry of mosquitoes and the use of different repellents such as N,N-diethyl-meta-toluamide (DEET) are other effective methods to prevent contact with mosquitoes.

Developing a vaccine against malaria is difficult because of the inaccessibility of the malarial parasites from an immune attack by replicating inside red blood cells; generally poor immune response to key antigens, compared with the level required for effective

immunity; and high levels of polymorphisms in antigens that are targets of protective responses. According to the Jordan Report, there are 351 vaccines in development, of which 75% of those in phase III trials are attempting to induce full immunity using either recombinant or synthetic subunits.

**Babesiosis**

Babesiosis is a malaria-like illness that is mostly caused by a tick bite. It is a zoonotic disease; the main animal reservoirs are rodents and cattle. More than 100 species of *Babesia* with different animal reservoirs have been identified. However, human disease is mostly caused by the bovine species (*B bovis* and *B divergens*), particularly in Europe, and by the rodent (*B microti*) species in the United States. New emerging species have been identified such as the WA-1 in Washington state and California and the MO-1 in Missouri.

**Epidemiology**

The disease is caused by the bite of the *Ixodes* tick, which also transmits Lyme disease and human granulocytic anaplasmosis. The tick has 3 stages (larva, nymph, adult) and requires a blood meal to mature between stages. Babesiosis disease ends with humans, who get the infection by bite at the nymph stage. Rarely, babesiosis has resulted from blood transfusion. The possibility of perinatal and transplacental transmission has also been considered.

*Babesia* transmission has been found in 2 major geographic areas, with distinct forms of disease:

**Table 308-2** Chemoprophylaxis for Malaria<sup>a</sup>

DRUG	DOSE
<b>Areas with chloroquine-sensitive <i>Plasmodium</i> species</b>	
Chloroquine Phosphate	5 mg/kg base once/week, up to adult dose of 300 mg base
<b>Areas with chloroquine-resistant <i>Plasmodium</i> species</b>	
Atovaquone/Proguanil	5–10 kg: 1–8 tab once/week 11–20 kg: 1 peds tab/day 21–30 kg: 2 peds tabs/day 31–40 kg: 3 peds tab/day >40 kg: 1 adult tab/day
OR	
Mefloquine	11–20 kg: ¼ tab once/week 21–30 kg: ½ tab once/week 31–45 kg: ¾ tab once/week >45 kg: 1 tab once/week
OR	
Doxycycline	2 mg/kg/day, up to 100 mg/day
<b>Alternatives</b>	
Primaquine	0.6 mg/kg base daily
OR	
Chloroquine phosphate PLUS Proguanil	5 mg/kg base once/week, up to 300 mg base 2–6 yrs: 100 mg once/day 7–10 yrs: 150 mg once/day >10 yrs: 200 mg once/day

<sup>a</sup>Chemoprophylaxis should begin 2 weeks before arrival in the area with endemic infection (except doxycycline and atovaquone-proguanil, which should be started 1–2 days before arrival). These medications should be continued, for 1 week when receiving atovaquone-proguanil and 4 weeks when receiving the other medications, after the departure from the endemic areas.

Modified in part from Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015.

Europe and the United States. In Europe, the disease is mostly caused by bovine species, particularly *B divergens*. Patients affected with this species are mostly those who have undergone splenectomy. The disease is transmitted by the tick *Ixodes ricinus*. The disease is typically severe and has high mortality rates. European cases were reported in Yugoslavia, France, Germany, Spain, Sweden, Ireland, Great Britain, and the former Soviet Union.

In the United States, however, most cases are caused by *B microti*. The white-footed mouse is the reservoir of infection. The vector of transmission is the tick *Ixodes scapularis*. The majority of cases occur in the northeastern part of the country as well as the upper midwestern region. This includes islands and coastal areas near Massachusetts, New York, New Jersey, Rhode Island, and Connecticut as well as Wisconsin and Minnesota. Cases have also been reported in other states. Most tick bites go unnoticed and only 10% to 20% of affected individuals recall a tick bite. The majority of cases occur between May and August, the time of nymph abundance and peak outdoor activity. The tick should attach for at least 24 hours to

transmit infection. The majority of infected patients in the United States are immunocompetent. Most infections are asymptomatic. The incubation period is 1 week to several months.

Babesiosis cases have also been reported in other parts of the world including Taiwan, the Canary Islands, Egypt, South Africa, Mexico, and China.

Risk factors for severe disease and mortality caused by babesiosis include age older than 40 years, asplenia, HIV infection, and immunosuppressive therapy including steroids. The disease is particularly overwhelming in patients who have undergone splenectomy.

### Pathogenesis and Life Cycle

The life cycle of *Babesia* is somewhat similar to that of malaria. The parasite multiplies sexually in the vector and asexually in the infected mammal or human. During transmission, humans acquire sporozoites from the salivary gland of the *Ixodes* vector. The sporozoites invade the red blood cells and differentiate into trophozoites, which replicate asexually by budding and release merozoites. This will lead to lysis of red cells and hemolytic anemia. Released merozoites subsequently attack other red blood cells and the cycle goes on. Autoimmune mechanisms may also be implicated in hemolysis as evidenced by a positive Coombs test result in some patients with babesiosis.

In addition to hemolysis, intraerythrocyte multiplication leads to vascular stasis secondary to increased adherence to endothelial cells. This results in ischemic damage in different organs including the liver, spleen, heart, and brain. Hemolysis and vascular injury may also cause renal insufficiency. Increased proinflammatory cytokine release has also been demonstrated in patients. All these may contribute to pulmonary edema and a sepsislike picture may eventually develop.

The spleen plays an essential role in limiting babesiosis by removing deformed erythrocytes. This explains the high levels of parasitemia and severe disease that occur in patients with splenectomy. Both cell-mediated and humoral immunity are demonstrated during infection. However, the cell-mediated immune responses via CD4 cells and interferon- $\gamma$  are known to play a critical role in controlling babesiosis.

### Clinical Manifestations

Most pediatric babesiosis cases are subclinical or mild. In symptomatic patients, the clinical manifestations range from nonspecific symptoms to severe hemolysis. The typical symptoms are characterized by a flulike illness, with gradual onset of malaise, fatigue, and anorexia followed by episodes of fever associated with chills, sweats, myalgia, headache, and vomiting. Less commonly, conjunctival injection, meningismus, altered sensorium, and nonproductive cough may be present. The nonspecific symptoms may cause a delay in diagnosis. Symptoms may last for several weeks or sometimes for months. Patients who are coinfecting with *Borrelia burgdorferi*, the agent of Lyme disease and/or *Anaplasma phagocytophila*, the agent of human granulocytic anaplasmosis, tend to develop more prolonged symptoms. HIV-infected patients have also been reported to have prolonged clinical course.

Infection with *B divergens* is associated with fulminant illness.

Immunodeficient patients and those with splenectomy develop severe infection characterized by hemolytic anemia, jaundice, and dark urine. Severe babesiosis may also occur in post-transfusion cases. Many signs and symptoms are similar to those of malaria. Lactate dehydrogenase levels will be elevated. The hemolysis seen in babesiosis is milder than that of malaria. As a result of hemolysis, renal insufficiency with anurea and azotemia may develop. Other possible complications of babesiosis in this group of patients include hypotension, shock, disseminated intravascular coagulation, heart failure, and acute respiratory distress syndrome.

### Diagnosis

The diagnosis of babesiosis is made by demonstrating the organism in blood smears. Similar to malaria diagnosis, thick and thin smears should be prepared using Wright and Geimsa stains. *Babesia* species may sometimes be difficult to differentiate from *Plasmodium* species. However, the differentiating feature of *Babesia* species include the presence of a cluster of 4 small merozoites called the *tetrads* in red blood cells. Because the red cells tend to be infected repeatedly, multiple parasites may be present in a single cell. The occasional presence of 3 chromatin dots in a single parasite is another differentiating feature. In addition, no pigment is seen in *Babesia* smears; schizonts and gametocytes are also absent.

Serology should be considered when blood smears are nondiagnostic such as in cases with low parasitemia. The most sensitive test is the indirect immunofluorescent assay available in reference laboratories. PCR testing has also become available for the diagnosis of babesiosis. The test is more sensitive than blood smear. It may also be used for monitoring therapy and for epidemiologic surveillance.

### Treatment

The recommended treatment regimens for symptomatic infection are clindamycin plus oral quinine or atovaquone plus azithromycin for 7 to 10 days. Exchange transfusion should be considered for fulminant cases with severe hemolysis and high-grade parasitemia (>10%).

### Prevention

Recommendation for prevention of tickborne infections should be followed. Tick-infested areas should be avoided if at all possible, particularly during the May to September period. Wearing clothing that covers the arms, legs, and other exposed areas and tucking pants into socks or boots should be considered. Tick and insect repellants that contain DEET may be considered, but repeat applications may be needed. Tick-toxic agents such as permethrin may be sprayed on clothes and shoes but not the skin. In addition, people should inspect themselves and the bodies of their children as well as all clothing for ticks after possible exposure. Exposed hairy areas including the scalp and behind the ears should be thoroughly inspected. If a tick is found, it should be grasped with tweezers close to the skin and gently pulled out

straight. Pets should also be inspected every day for ticks; if identified, the ticks should be removed.

## NEMATODE INFECTIONS

### Trichinellosis (*Trichinella spiralis*)

The infection is caused by the roundworm of the genus *Trichinella*. There are 6 species that can infect humans and animals but the most common is *Trichinella spiralis*. In contrast to other parasitic infections, trichinellosis (or trichinosis) is more common in Europe and America than in Asia and Africa.

### Epidemiology

*Trichinella* can infect carnivorous animals, particularly scavengers. Humans acquire infection by eating raw or inadequately cooked meat containing *Trichinella* cysts. Domestic pigs are the most common source of infection in America and Europe. The incidence of trichinellosis has been declining steadily in the United States. This is believed to be a result of new laws governing production and processing of pork, including the feeding of swine; routine slaughterhouse surveillance; and improved public awareness. Undercooked wild game, especially bear, seal, and walrus meat has emerged in recent years as the most common cause of trichinellosis. *T nativa* is the subspecies most frequently associated with arctic sources. Consumption of horse meat has also been associated with trichinellosis. The incubation period is 1 to 2 weeks.

### Life Cycle and Pathogenesis

After the ingestion of infected meat by humans, the larvae are liberated from the cysts in the intestine and mature into adults in epithelial cells. The adult male dies after mating. The fertilized adult female produces embryos at a rate of 1 every 30 minutes during her life span of 4 to 16 weeks. The larvae then enter the bloodstream via the intestinal lymphatics and disseminate to different organs. *Trichinella* larvae survive only in the skeletal muscles and become encysted in 2 to 3 weeks. The most frequently affected muscles are those of the limbs and the diaphragm, followed by the tongue, intercostals, extrinsic muscles of the eye, and laryngeal and paravertebral muscles.

### Clinical Manifestations

Most infections are asymptomatic. The severity of infection correlates with the number of ingested larvae. The infection has 2 stages. The first is the intestinal stage, which begins 24 hours after infection and lasts for 1 to 7 days. During this phase, patients may be asymptomatic or experience gastrointestinal symptoms such as nausea, vomiting, diarrhea, constipation, and abdominal pain. The muscle stage starts after the first week and correlates with dissemination of larvae from the intestine to the bloodstream. The typical symptoms consist of the triad of myalgia, eyelid edema, and eosinophilia. This phase may last 1 to 5 weeks or longer. The myalgias may be prominent and mimic rheumatic pain. Muscle pain, tenderness, swelling, and weakness can occur. The larvae may remain viable in the muscles for years. Calcification may occur after several months and may be detected on radiography. The edema often involves the face, eyelids,

and conjunctiva. Other common associated findings are high and prolonged fever, which is rarely seen in parasitic infections, weakness, and malaise. Other less frequent findings include headache, subconjunctival hemorrhages, retinal hemorrhages, splinter hemorrhages under fingernails, facial flushing, urticarial or macular rashes, hoarseness, dyspnea, and dysphagia. The clinical manifestations of trichinellosis are caused by either larval invasion or host immune response to the parasite.

The most common cause of death in cases of severe trichinellosis is myocarditis with subsequent heart failure and cardiac arrhythmias. Cardiac involvement usually occurs in the second to third week of infection. Severe trichinellosis may also be associated with encephalitis, meningitis, focal neurologic deficits, bronchopneumonia, and nephritis.

### Diagnosis

The diagnosis of trichinellosis should be suspected in patients with a suggestive clinical history, including consumption of inadequately cooked meat, particularly pork, and eosinophilia. The presence of clinical symptoms in other patients who shared the same food makes the diagnosis stronger. Eosinophilia usually appears during the second week of the muscle phase and may be as high as 70%. Muscle enzymes such as creatine kinase and lactate dehydrogenase may be elevated as may be immunoglobulin levels.

Serologic tests are used to make the diagnosis of trichinellosis. Different assays are used including ELISA, indirect immunofluorescence assay, and latex agglutination. ELISA is the most sensitive assay. Serologic tests are only helpful after the second week of infection when antibody titers start to rise. Testing of paired acute and convalescent serum samples is diagnostic. Antibody levels may remain positive for more than 1 year after clinical improvement.

The most definitive diagnostic test is finding larvae microscopically in muscle biopsy. However, this only occurs after the first 2 weeks after ingestion. The number of larvae per gram of muscle has been used as a guide of severity of infection. When tested, specimens should be fresh and compressed between 2 microscope slides or should be digested by artificial gastric juice to increase yield. Suspected infected meat sources may also be tested for larvae. Recently, PCR testing was used to detect *Trichinella*-specific DNA in muscle biopsy specimens. The test was found to be sensitive and specific, but its availability is limited.

### Treatment

Mebendazole and albendazole are recommended for treatment of trichinellosis with comparable efficacy. Mebendazole is given at a dose of 200 to 400 mg 3 times a day for 3 days, then 400 to 500 mg 3 times a day for 10 days. Albendazole may achieve higher tissue levels; the dose is 400 mg twice daily for 10 to 15 days. Both drugs are ineffective for larvae already in the muscles. Coadministration of steroids such as prednisone is indicated in severe cases especially for those with cardiac and CNS involvement. People who have recently ingested *Trichinella*-contaminated meat should be treated with mebendazole or albendazole.

### Prevention

Control can be achieved by thoroughly cooking pork and game meat. Freezing is also effective in killing larvae in meat. The encysted larvae of *Trichinella* are killed by heating to a temperature of 77°C or freezing at –15°C for 3 weeks, which is available via home freezers. Freezing pork meat at –23°C for 10 days is also effective, but *Trichinella* in arctic species may be resistant and may remain viable. Transmission to pigs can be decreased by not feeding them unprocessed garbage and by effective rat control.

### Hookworm Infections (*Ancylostoma duodenale* and *Necator americanus*)

Hookworm infections are widely prevalent in tropical and subtropical regions. Factors that favor spread of hookworm in these regions include warm climate, abundance of rain, soil contaminated with human feces, and people walking barefoot. The 2 most common hookworms are *Ancylostoma duodenale* and *Necator americanus*.

### Epidemiology

The prevalence of hookworm species varies in different geographic areas. *A. duodenale* is prevalent in Mediterranean countries, India, Pakistan, Iran, and the Far East. *N. americanus* is prevalent in North and South America, central Africa, Indonesia, and islands of the South Pacific. Humans are the only reservoir of infection. Hookworm eggs excreted in stool hatch in soil within 1 to 2 days, forming larvae that mature within approximately 1 week into infective larvae. These larvae may persist for weeks or even months in soil if appropriate temperature (23°C–33°C) and conditions such as moisture are found.

Humans acquire infection after percutaneous penetration of larvae. However, *A. duodenale* may also be acquired via the oral route or human milk. As few as 3 larvae are enough to cause infection. From the skin, larvae reach the lungs and then the tracheobronchial tree. Then the larvae are coughed and swallowed, reach the small intestine, and develop into adult worms. Eggs appear in the stools 1 to 3 months after infection.

### Clinical Manifestations

Persistent eosinophilia is a common finding. The symptoms and signs correlate with the stage of infection. The earliest findings result from larval penetration of the skin. Itching, focal eruptions with or without edema or enlargement of adjacent lymph nodes is referred to as “ground itch.” Pulmonary migration is associated with mild respiratory symptoms such as cough. However, in severe cases, Loeffler syndrome may develop.

In the intestinal phase, patients may complain of abdominal pain, nausea, vomiting, increased flatulence, diarrhea, and constipation. However, the main symptoms of hookworm infection are related to iron-deficiency anemia and loss of plasma protein. A single worm of *A. duodenale* sucks 0.01 to 0.04 mL of blood per day, whereas *N. americanus* sucks 0.05 to 0.3 mL of blood per day. Greater blood losses occur around the worm attachment site. Malnutrition and blood loss with iron-deficiency anemia are the most significant

complications of heavy infection in normal hosts. The severity of anemia and malnutrition is higher in children infected with *A duodenale* than in those infected with *N americanus*. Anthelmintic therapy improves nutritional status and hemoglobin levels in these patients.

### Diagnosis

Hookworm infection is diagnosed by identification of eggs in stools. The eggs of *A duodenale* and *N americanus* are morphologically indistinguishable. However, the species can be identified using PCR testing. Adult worms are rarely seen. Larvae are rarely seen in stool samples when the samples are left at room temperature for 24 hours or in patients with constipation. Stool smears are often negative in early stages of infection because of delayed egg excretion. Stool concentration techniques may be needed in patients with mild infection. Repeat stool examinations may also be needed.

### Treatment

Malnutrition and anemia may need correction including iron supplementation. Albendazole, mebendazole, and pyrantel pamoate are the drugs of choice for treating hookworms in children and adults. Albendazole is not approved by the FDA for treatment of hookworm infections. Mebendazole is no longer available in the United States. Albendazole is given at 400 mg once. The dose of mebendazole is 100 mg twice daily for 3 days or 500 mg once; the dose of pyrantel pamoate is 11 mg/kg (maximum 1 g) for 3 days. If given to children younger than 2 years, the doses of mebendazole and albendazole may be reduced by half. Repeat stool examination is recommended 2 weeks after treatment; if positive, retreatment should be considered. A 3-day course of nitazoxanide may be effective in treating hookworms, but no comparative data with albendazole are available.

### Prevention

Proper disposal of human feces is essential. All patients with known infection should be treated to decrease environmental contamination. Individuals at high risk of infection including children and agricultural workers in endemic areas should be screened for the presence of hookworms in stools and appropriately treated.

Education of the population regarding footwear may reduce transmission of hookworm infection.

### Ascariasis (*Ascaris lumbricoides*)

Ascariasis is the most prevalent helminthic infection worldwide. It is estimated that more than 1.4 billion people are infected with ascariasis. It is most common in the tropics and areas of poor sanitation practices, including regions in which human feces are used for fertilization. In the United States, ascariasis is the third most common helminthic infection following hookworm and *Trichuris trichiura* infection. It is caused by *Ascaris lumbricoides*, the largest roundworm that infects humans.

### Epidemiology

The female adult worm measures 22 to 35 cm in length and 3 to 6 mm in diameter and resides in the lumen

of the jejunum and ileum. Females produce 200,000 eggs per day which are excreted in stools. Fertilized eggs become infective in soil 3 to 4 weeks after they are excreted. Human infection occurs by ingesting eggs from contaminated soil. Larvae hatch in the intestine, penetrate the intestinal wall, and migrate to the right heart, lungs, and bronchial tree. From there, the larvae ascend to the pharynx and are subsequently swallowed to mature into adult worms in the small intestine. Female worms begin laying eggs 2 to 3 months after exposure. The lifespan of the parasite is 6 months to 1 year.

### Clinical Manifestations

Most infections are asymptomatic. However, the burden of the disease is high because of the widespread prevalence of disease. Symptoms are caused by either the larval migration or the presence of the adult worm in the small intestine. Clinical features and complications are caused by direct tissue damage, the immune response of the host, obstruction, or malnutrition.

During larval migration, an acute transient pneumonitis known as *Loeffler syndrome* tends to occur 1 to 2 weeks after ingestion of the eggs. This syndrome is often associated with fever, marked eosinophilia, and other symptoms related to hypersensitivity such as urticaria. Nonspecific gastrointestinal symptoms occur in patients with ascariasis such as abdominal discomfort, nausea, vomiting, and diarrhea. Moderate to heavy infections in children may be associated with malnutrition and malabsorption of proteins, lactose, and vitamins. Heavy infection may also lead to acute intestinal obstruction caused by a mass of worms in the bowel lumen. The obstruction most frequently occurs at the ileocecal valve. Most affected patients are young children (1–5 years old). Other intestinal complications in endemic areas include ileocecal intussusception, volvulus, intestinal gangrene, and perforation. Intestinal obstruction is the primary cause of death in ascariasis.

Worm migration into the biliary tree can cause biliary colic, cholecystitis, and ascending cholangitis. Biliary strictures and hepatic abscesses are other less frequent complications. Pancreatitis may also result from migration of the adult worm into the pancreatic duct. Worm migration to the appendix may lead to appendicitis. Migration may occur through body orifices such as the mouth, nose, anus, and lacrimal duct. Worm migration is stimulated by stress factors such as fever, intercurrent illness, diarrhea, spicy foods, and anesthesia. Some anthelmintic agents may also stimulate worm migration.

### Diagnosis

Diagnosis of ascariasis is made by demonstration of characteristic eggs in stools using direct microscopy. Eggs may not appear in the stools until after at least 40 days of infection. Usually 1 stool sample is sufficient to confirm the diagnosis. Sometimes adult worms are passed and provide a clue to the diagnosis. Peripheral eosinophilia occurs during the pulmonary phase of infection. In addition, eosinophils and occasionally *Ascaris* larvae may be demonstrated in sputum samples. Imaging studies may demonstrate worms in

cases of intestinal obstruction as well as in cases of hepatobiliary or pancreatic ascariasis. Serologic testing is not helpful in diagnosis but can be used in epidemiologic studies. Serum IgG antibodies are not protective.

### Treatment

The recommended treatment of symptomatic and asymptomatic infections is albendazole in a single dose (400 mg), mebendazole 100 mg twice daily for 3 days, or ivermectin 200 µg/kg in a single dose. Although data suggest that these drugs are safe, experience with these drugs is limited in children younger than 2 years. Thus, the risk and benefits of treating ascariasis should be considered in this age group. Pyrantel pamoate and nitazoxanide are also effective in treatment of ascariasis. Reexamination of stools after 2 weeks is helpful to assess the effectiveness of the therapy.

Cases with suspected intestinal or biliary obstruction should be managed conservatively with nasogastric suction and intravenous fluid. Piperazine solution (75 mg/kg per day, maximum 3 g/d), which may be given by a nasogastric tube, may relieve obstruction caused by heavy intestinal worm burden. Piperazine paralyzes the worm and prevents migration during passage through the intestine. Piperazine is not available in the United States, and is not approved by the FDA for this indication. Conservative management to alleviate obstruction is followed by anthelmintic therapy with either albendazole, mebendazole, or ivermectin. Nitazoxanide may also be used. Albendazole, ivermectin, and nitazoxanide are not FDA labeled for use in ascariasis. Pyrantel pamoate and piperazine are antagonistic and should not be given together.

Surgery is recommended if medical therapy is not successful at relieving obstruction or in complications such as volvulus peritonitis or perforation. During laparotomy for obstructive cases, the small bowel should be “milked” down to the cecum, avoiding incision of the bowel wall. Endoscopic retrograde cholangiopancreatography is used to extract worms in hepatobiliary cases.

### Prevention

Prevention of reinfection is a challenging problem because of the abundance of *Ascaris* eggs in soil. Sanitary disposal of human feces is essential to prevent soil contamination, particularly near children’s play areas. In some areas, educational programs aimed at stopping the use of human feces as a fertilizer may be needed. In such areas, people should also be educated about proper food washing and cooking.

Mass deworming programs with a single dose of mebendazole or albendazole have been used in some communities in areas in which ascariasis is endemic. School children are the target in most programs. These programs are used every 3 to 4 months and are aimed at treating and preventing morbidity in children as well as decreasing the worm burden in the community. In highly endemic areas where more than 50% of the population is infected, the whole population may be targeted for mass treatment.

## Toxocariasis

### Visceral larva migrans

Toxocariasis is caused by the *Toxocara* species. Visceral larva migrans (VLM), which is also called toxocariasis, is caused by migration of the larvae in the viscera of the host. This syndrome is caused by the dog ascarid, *Toxocara canis* and less frequently by the cat ascarid, *Toxocara cati*. Other nematodes such as *Baylisascaris procyonis*, the common raccoon roundworm, rarely cause VLM. The life cycle of *T canis* and *T cati* in their respective animal species is similar to that of *Ascaris lumbricoides* in humans. Humans are considered unusual hosts for *T canis* and *T cati*. Thus, infection with these parasites causes failure to complete the life cycle or aberrant migration of larvae. Because the parasite fails to mature in humans, it remains alive in the body for months to years.

**EPIDEMIOLOGY.** Humans acquire infection by ingesting soil contaminated with infective eggs of the parasites. The disease is endemic in areas with dogs. The highest number of reported cases of VLM is in the United States. A large number of pets, particularly puppies, are infected and routinely contaminate yards, school playgrounds, and sandboxes. Most affected patients are children 1 to 4 years of age. History of pica is common. The eggs are not immediately infective after shedding by dogs. However, after about 3 weeks in the soil, they can cause infection in humans. Hot, humid regions are associated with persistence of eggs in soil and increased risk of infection. The disease may be found anywhere dogs are present. The highest rates of transmission are in the southern United States, particularly in rural areas. However, infection can also be acquired in urban areas. It has been estimated that 20% of dogs and 98% of puppies are infected.

**PATHOGENESIS AND LIFE CYCLE.** The reservoir of *T canis* infection is the female dog. The disease is reactivated during pregnancy and then transmitted to puppies via the placenta or breast milk. The puppies shed eggs in the surrounding environment. When humans ingest these eggs, the larvae hatch in the intestine and spread via the portal circulation to the liver and then to the systemic circulation. Because the parasite cannot mature, it passes through different organs and tissues before it overwhelms the immune system. The most commonly involved organ is the liver. However, the lungs, heart, kidneys, eye, skeletal muscles, and brain may also be involved. During tissue migration, granulomas are formed and a significant host immune response is demonstrated by peripheral eosinophilia and elevated IgE levels. The manifestations and severity of infection depend on the immune status of the host, the burden of infection, and the site of involvement.

**CLINICAL MANIFESTATION.** Most patients who are mildly infected are asymptomatic. Incidental findings or eosinophilia, hepatomegaly, and history of pica in these patients may prompt a search for the diagnosis of toxocariasis. Symptomatic children with VLM usually present with fever, leukocytosis with eosinophilia, hypergammaglobulinemia, and hepatomegaly. Splenomegaly and lymphadenopathy are other associated findings. Patients may also have allergic manifestations such as urticaria, rhinorrhea, and asthma. Pulmonary

infiltrates may be evident on radiographs. Constitutional symptoms such as anorexia, weakness, failure to gain weight, myalgia, arthralgia, and nocturnal sweats may also be present. Neurologic symptoms include irritability and seizures but are less frequent. Other reported findings include myocarditis, congestive heart failure, pleural effusion, eosinophilic ascitis, and meningoencephalitis.

Ocular involvement usually affects patients older than 4 years of age; when it occurs, usually no other systemic involvement is seen. This suggests that the ocular and visceral forms of oxocariasis are 2 distinct entities. This form of disease, which is seen in older children with no history of pica, is called *ocular larva migrans* (OLM). Patients often have a unilateral solitary posterior retinal lesion. A granulomatous mass or multiple lesions may be seen. Lesions are painless and some are asymptomatic and found incidentally on routine retinal examination. Common symptoms include strabismus, visual impairment, unilateral loss of vision, and leukocoria. Complications of OLM include chronic endophthalmitis, retinal detachment, keratitis, uveitis, iritis, vitreous abscess, optic neuritis, and retinal tracks with larvae. Some cases in the past, such as cases of retinoblastoma, were misdiagnosed and managed as intraocular tumors. Patients with OLM typically do not have other organ-systemic involvement.

**DIAGNOSIS.** A definitive diagnosis of VLM requires demonstration of the larvae in tissue sections, but this is rarely needed. In most cases, the diagnosis is based on clinical findings and serologic testing. In systemic toxocariasis, eosinophilia is a consistent finding. The total white cell count may be as high as 30,000/ $\mu$ L ( $30 \times 10^9$ /L) with up to 80% eosinophils. Other consistent and nonspecific laboratory findings include hypergammaglobulinemia with high IgE levels, sometimes 10 to 15 times the normal levels as well as elevated isohemagglutinins to the A and B blood groups. During the pulmonary phase of involvement, eosinophils may be detected in respiratory secretions. With CNS involvement, CSF specimens may also show eosinophils.

Serologic testing is used to confirm the diagnosis of VLM. ELISA is the most frequently used test and has high sensitivity and specificity. Western blot and immunofluorescence tests have also been used. Serologic tests are often negative in OLM.

**TREATMENT.** Infections in most patients are self limited and require no specific treatment. Treatment is recommended for patients with symptoms and those with systemic form of the disease. The recommended drug for treatment in children is albendazole. The drug has been approved by the FDA but not for this clinical indication. It is given at a dose of 400 mg twice a day for 5 days. Corticosteroids are indicated for cases with severe cardiac and CNS involvement. Ocular involvement is treated with anthelmintic therapy, surgery, steroids, or a combination of these modalities. Diethylcarbazine is another alternative. The drug is not FDA approved but a 3-week course is recommended by the WHO for this indication. The dose is 3 mg/kg twice daily. It is common to start the dose at 1 mg/kg twice daily and then increase gradually to decrease allergic reactions induced by dying larvae.

**PREVENTION.** Underlying causes of pica in children should be corrected. Cat and dog feces should be properly disposed of. Sandboxes that are in use should be covered. Regular anthelmintic therapy for puppies and kittens may prevent secretion of eggs in feces and subsequent potential transmission to toxocariasis.

## CESTODE INFECTIONS

### Taeniasis and Cysticercosis (*Taenia solium* and *Taenia saginata*)

#### Epidemiology

Humans are the only definitive host for 2 *Taenia* species, *Taenia solium* and *Taenia saginata*. Taeniasis is caused by the adult worm of both species whereas cysticercosis is caused by the larval stage of only *T solium* (not *T saginata*). Both species have a worldwide distribution, with a higher prevalence in areas in which undercooked beef or pork are customarily consumed. *T saginata* is found most commonly in some states of the former Soviet Union, the Near East, and Central and Eastern Africa, and is less commonly found in Europe, Southeast Asia, and South America. *T solium* is prevalent in Mexico, Central and South America, Africa, and Southeast Asia, and very rare in Muslim countries. In the United States, human infections are usually found in immigrants from areas with high disease prevalence or travelers who consume undercooked meats in endemic areas. Although most cases of human cysticercosis in the United States have been imported, it has been found that cysticercosis can be acquired from patients or immigrants from endemic areas who have the adult stage of *T solium* infection in the intestine.

#### Life Cycle

Taeniasis is a human infection caused by the adult stage of *T solium* or *T saginata*. Humans acquire infection by ingesting undercooked beef (for *T saginata*) or pork (for *T solium*) that contained cysticerci in the muscle. Inside the human intestine, protoscolices are released from the cysticerci and attach to the intestinal wall with suckers and hooks. The protoscolices become the head of the tapeworm, later develop by forming the proglottids, and mature into an adult tapeworm over a period of 2 months. This maturation occurs inside the human small intestine where the tapeworms can survive for years. As the adult tapeworm develops, mature proglottids are produced and later become gravid. The gravid proglottids that contain egg-filled uterus detach from the tapeworm, migrate to the anus, and are passed in the stool. The eggs inside the gravid proglottids are released in the stool after the proglottids are passed with the feces. In the environment, eggs can survive for days to months. The intermediate hosts, cattle for *T saginata* and pigs for *T solium*, become infected after ingesting vegetation contaminated by eggs or gravid proglottids. The oncosphere hatches inside the animal intestine, invades the intestinal wall, and later migrates through the hematogenous or lymphatic system to the straight muscles. The oncosphere develops into cysticerci in the animal muscle. The cycle completes when humans ingest undercooked meats that contained cysticerci

in the muscle. The cysticerci can survive in the muscle of the animal for years.

Cysticercosis is an infection in humans that occurs when a human becomes infected with the larval stage of *T solium*. Infection occurs after embryonated eggs are ingested by the human. This can occur either by ingesting food contaminated with human feces or autoinfection. In the case of autoinfection, a human becomes infected after ingesting eggs produced by that tapeworm via oral-fecal contamination or possibly from proglottids that are carried backward into the stomach through reverse peristalsis. Inside the human intestine, the oncosphere hatches, penetrates the intestinal wall, and migrates via circulation or lymphatic channels to various tissue sites. Cysticerci may develop in any organ, more commonly the brain, subcutaneous tissue, eye, and liver, resulting in cysticercosis.

### Clinical Manifestations

Taeniasis is often asymptomatic. Patients may experience minimal gastrointestinal tract symptoms such as nausea, diarrhea, and abdominal pain or discomfort. The main symptom usually is the intermittent passage of the proglottids either with the stool or spontaneously. The proglottids may enter the appendix, common bile duct, or pancreatic duct and cause obstruction. A large number of worms can also cause intestinal obstruction.

Cysticercosis can affect humans at any age. Most of the infections occur during the third or fourth decades of life; about 10% of cases occur in children. Cysts can be found anywhere in the body, most commonly in the CNS. Clinical manifestations usually depend on location, stage, and number of cysts as well as the host immune reaction. Symptoms frequently become evident when an inflammatory response develops around a degenerating cyst after a variable period. Cysticercosis in children manifests differently than in adults. The most serious manifestation of cysticercosis is neurocysticercosis or cysticercosis of the CNS. In infants, the initial clinical manifestation of neurocysticercosis is generalized seizure. In most cases, the cysts resolve spontaneously; however, in about one-third of cases, the cyst may remain as a granuloma that later becomes calcified. Children with calcified granuloma in the CNS have a high risk of developing chronic seizures. In adolescents and young adults, neurocysticercosis may remain clinically silent through multiple stages of infection until it becomes a calcified granuloma that eventually serves as foci causing epilepsy, frequently after 25 years of age. Neurocysticercosis in adults manifests differently from that seen in children and generally is asymptomatic. Patients frequently have cysts in more than 1 location. Cysts can be seen in various stages, and some patients may have both active and inactive cysts at the same time. Symptoms, if any, occur mainly because of a mass effect, an inflammatory response, or obstruction of the ventricular system of the brain. The most common form of neurocysticercosis in adults is the active parenchymal cyst. Patients may present with severe headache and focal or generalized seizure. Physical examination findings usually are normal without any neurologic deficit

symptoms. A calcified parenchymal cyst is found less commonly and is usually asymptomatic. However, clinical symptoms such as focal neurologic deficit and seizure may develop as perilesional edema occurs. The other less common forms of neurocysticercosis are subarachnoid cysts, ventricular cysts, and spinal cysticercosis. Patients with subarachnoid cysts may present with visual field defect or cranial nerve palsies as a result of cranial nerve entrapment from meningeal inflammation and irritation. Hydrocephalus or signs and symptoms of increased intracranial pressure are a common manifestation in patients with ventricular cysticercosis. Spinal cysticercosis is rare and is found in only about 1% to 3% of all neurocysticercosis cases. Symptoms depend on the location of the cyst and may not be distinguishable from other spinal cord lesions.

Cysticercal encephalitis is characterized by encephalitis and generalized brain edema occurring as a result of a severe immune response of the human host to massive amount of cysts in the brain parenchyma. Symptoms include fever, headache, vomiting, impaired consciousness, reduced visual acuity, and seizure. This reaction may develop spontaneously or after treatment with medication that leads to degeneration of large numbers of cysts at the same time. Cysticercal encephalitis occurs most commonly in children and young women.

Extraneural cysticercosis typically involves eye, muscle, and subcutaneous tissue. Ocular cysticercosis is found in about 1% to 3% of all cases. Generally, patients are asymptomatic; however, symptoms may become apparent as the cyst degenerates with surrounding inflammatory reaction. In patients with neurocysticercosis, it is recommended that ocular cysticercosis should be excluded before initiating treatment. Patients with subcutaneous or intramuscular cysticercosis usually are asymptomatic. Some patients may notice small palpable nodules that may be inflamed or may experience muscle pain. Subcutaneous and muscular cysticercosis is found more commonly in patients from Asia and Africa than in those from Latin America.

### Diagnosis

Diagnosis of taeniasis is made via microscopic identification of eggs or proglottids in the stool. This may not be possible during the first 3 months of infection before maturation of the adult worm and production of gravid proglottids. Eggs of *T solium* are microscopically indistinguishable from those of *T saginata* or of other tapeworm species, especially the *Echinococcus*. The species can be determined by microscopic examination of the gravid proglottids and scolex, if available.

The definitive diagnosis of cysticercosis is made by demonstration of the cysticercus in the involved tissue. Demonstration of eggs or proglottids in the stool specimen may help support the diagnosis but does not prove the presence of cysticercosis. For neurocysticercosis, CT scan and MRI are the most reliable imaging techniques. MRI has the advantage of better visualization of ocular, ventricular, and subarachnoid cysts. It also clearly demonstrates the degree of edema and inflammation as well as the viability of the cysticercus. The advantage of CT is better detection of a

granuloma or calcification, which can be missed on MRI. Several serologic studies have been developed for the diagnosis of cysticercosis. The serologic test of choice acknowledged by WHO and the Pan American Health Organization for confirming diagnosis of cysticercosis is the CDC immunoblot assay with purified *T solium* antigens. It has 100% specificity and 50% to 97% sensitivity depending on the number and stage of the cysticerci. The enzyme immunoassay (EIA) technique is another serologic study available for the diagnosis of cysticercosis. Compared with the immunoblot, EIA has less sensitivity and specificity. In addition, EIA also can cross-react with other helminthic infections such as echinococcosis and filariasis; hence, the EIA is less preferable than the immunoblot technique. To date, no available serologic test has been developed that can distinguish between active and inactive infection. Both the cysticercosis immunoblot and EIA kit are commercially available in the United States.

### Treatment

Praziquantel is the drug of choice for the treatment of taeniasis caused by both *T solium* and *T saginata*, and is highly effective in eradicating the adult-stage (intestinal stage) tapeworm. Praziquantel is not approved for this indication, but the recommended dose for children is 5 to 10 mg/kg as a single dose.

Niclosamide and nitazoxanide are alternative agents; niclosamide is not available commercially in the United States.

Treatment of cysticercosis is complicated, especially for ocular and neurocysticercosis. The appropriate treatment for a patient depends on location of the cyst, viability of the cyst, the host immune response, and the presence or absence of symptoms. In general, the widely accepted cysticidal agents are albendazole and praziquantel. For neurocysticercosis, treatment is generally not recommended for the asymptomatic patient with a nonviable single parenchymal cyst that is evidently destroyed by the host immune response. In children with viable cysticercus with minimal or no surrounding inflammatory response, a cysticidal agent should be given to prevent further perilesional damage and to reduce the risk of developing chronic seizure. After initiating treatment, patients may develop a treatment reaction as a result of sudden destruction of the cysticerci. This is usually accompanied by an inflammatory reaction of the surrounding tissue. Clinical manifestations include severe headache and vomiting. The treatment reaction can be minimized with a corticosteroid (dexamethazone) 2 to 3 days before treatment initiation and during treatment with a cysticidal agent. The recommended dose for albendazole is 15 mg/kg per day (maximum dose of 800 mg/day) divided into 2 doses for 8 to 30 days. The treatment can be repeated as necessary. Praziquantel is an alternative cysticidal agent. The recommended dose for praziquantel is 50 to 100 mg/kg per day in 3 divided doses for 30 days. In general, albendazole is preferred over praziquantel because of its higher cysticidal activity, less interaction with anticonvulsants, and lower cost. An anticonvulsant agent is usually recommended for patients who present with seizures and patients

with multiple cysts with no history of seizure because of the risk of developing seizure activity after treatment initiation.

For cysticercal encephalitis, the initial goal of treatment is to reduce inflammation and cerebral edema with a corticosteroid or immunosuppressive agent. In these patients, treatment with a cysticidal agent should be deferred because the subsequent inflammatory response may worsen outcome, and in many cases, the cysticerci may resolve with antiinflammatory therapy alone. A small cyst located in the lateral ventricle can be treated effectively with an antihelminthic agent. Insertion of a ventriculoperitoneal shunt is recommended before initiating treatment in patients with hydrocephalus. In a child with a cyst in the fourth ventricle, attached to the middle cerebral artery, or compressing the optic chiasm, surgery is recommended before initiating a cysticidal agent. Children with subarachnoid cysts or a large cyst in the fissures should be treated for at least 30 days.

Surgery is the mainstay of treatment for ocular and spinal cysticercosis with no clearly defined role of anthelmintic therapy. For intraocular subretinal cysts, treatment with albendazole combined with a corticosteroid may be effective, whereas intraocular cysts located in the vitreous chamber should be removed surgically. An ophthalmologic examination should be performed in all cases to rule out intraocular cysts before initiating treatment. Children with symptomatic subcutaneous or muscular lesions should receive an antiinflammatory medication. Surgical excision of a solitary subcutaneous or intramuscular cyst may be considered for patients with persistent symptoms. Children with neurocysticercosis should be monitored with a brain imaging study after completion of treatment.

### Hymenolepiasis (*Hymenolepis nana*)

#### Epidemiology

*Hymenolepis nana* (dwarf tapeworm) is the most common cestode tapeworm infecting humans worldwide. Transmission is associated with poor sanitation and hygiene and usually is acquired by ingestion of food or water contaminated with human or rodent feces. Infections occur most commonly in children because of fecal-oral contamination. The highest disease prevalence is observed among institutionalized school-age children in developing areas of the world. An infection rate of 4% has been reported among school children in the rural southeastern part of the United States.

#### Life Cycle

*H nana* differs from all other cestodes because of its ability to complete its entire life cycle in a single host. The embryonated eggs are passed in the stool of an infected person and become infective immediately. Eggs are ingested by an intermediate arthropod host, and develop into cysticercoids inside the insect. Humans can acquire infection by ingesting embryonated eggs in contaminated food or water, via the hands, or cysticercoids-infected arthropods. In the human small intestine, the oncospheres (hexacanth larvae) are released from the eggs and penetrate into intestinal villus. The oncospheres develop into cysticercoids inside intestinal villus and later migrate back into

intestinal lumen. The cysticercoids evaginate their scoleces, attach themselves to the ileal part of intestinal mucosa, and mature into the adult worm. Eggs are released from the gravid proglottids of the adult worm and passed in the stool. Internal autoinfection can occur when eggs remain in the intestine. The eggs release their oncospheres, which penetrate the intestinal villus and continue the cycle without being passed to the external environment. The adult worms mature within 4 to 6 weeks.

### Clinical Manifestations

Most infections are asymptomatic. Patients with heavy infection may experience abdominal pain, nausea, vomiting, diarrhea, anorexia, weakness, irritability, and headache.

### Diagnosis

Diagnosis is made by the demonstration of eggs in stool specimens. Proglottids are rarely observed in stool. Detection of light infection may require a concentration technique and repeated examination. Peripheral blood eosinophilia may be found.

### Treatment

Although not approved by the FDA for this indication, praziquantel (25 mg/kg as a single dose) is the drug of choice. Close family members, especially siblings, should have their stool specimens examined. Simultaneous treatment of family members may be indicated. Stool examinations should be repeated 2 to 4 weeks after initiating treatment to document cure, especially in patients with heavy worm burden. Nitazoxanide is an alternative treatment option.

## Chapter 309

# PECTUS EXCAVATUM AND PECTUS CARINATUM

Jeffrey S. Mino, MD; Anthony Stallion, MD;  
Rosebel Monteiro, MD

## PECTUS EXCAVATUM

Pectus excavatum is a syndrome characterized by a concave depression of the sternum. It is the most common congenital chest wall deformity, affecting approximately 1 in 400 live births. Of those affected, 80% are boys. Family history is a risk factor for development of pectus excavatum, with 37% of patients having a first-degree relative with the condition. This congenital defect occurs from excessive growth of the costal cartilage, which displaces the sternum posteriorly. Phenotypically, the appearance resembles a funnel chest. The concavity is often asymmetric, with the right side usually more depressed than the left side, and can range in severity from a mild depression to a profound indentation.

## CLINICAL FEATURES

Pectus excavatum typically becomes problematic as children reach early adolescence, both as a result of embarrassment over the cosmetic appearance of the chest and occasionally of respiratory impairment from the defect. Rapid skeletal growth during this period tends to exaggerate the defect, and can cause a progression from barely noticeable to extremely prominent in the span of a few years. The severity of the defect usually does not increase after the age of 18, by which time most of the skeletal growth has occurred. Although most patients do not exhibit symptoms, some may have decreased exercise tolerance, easy fatigability, and frequent respiratory tract infections from decreased chest excursion and diminished inspirations. Displacement or rotation of the heart because of compression by the chest wall can occasionally lead to chest pain related to the defect, and total lung capacity is decreased.

Pectus excavatum has a known association with many disorders (Box 309-1). Scoliosis is present in approximately 15% of patients, and mitral valve prolapse may be seen up to 30% of the time. Pectus excavatum also has a strong association with Marfan syndrome and represents the most common chest wall abnormality seen in these patients.

Patients with pectus excavatum tend to have rounded shoulders and a protuberant abdomen with a slumped-over appearance, which is referred to as the *pectus posture*. This disfigurement can have serious psychological ramifications. Many patients with pectus excavatum suffer from psychosocial issues including social anxiety, problems with body image, depression, and avoidance of activities that expose the chest.

## EVALUATION

Examination of the child with pectus excavatum should include a thorough history and physical examination, with an attempt to rule out any associated

disorders that may have been previously undiagnosed. Auscultation of the chest may reveal a left displacement of the heartbeat and the click of a valve prolapse. A systolic cardiac murmur is also sometimes appreciated because of the closer proximity of the sternum to the pulmonary artery. Although lung sounds are typically clear, they are often diminished, and pulmonary function tests tend to demonstrate a restrictive pattern. A transthoracic echocardiogram may reveal diminished cardiac output from decreased stroke volume and mitral valve prolapse.

The severity of the defect is measured by the Haller index, which is the computed tomographic scan-measured transthoracic diameter divided by the sternovertebral diameter. An index of more than 3.5 is considered to be a severe defect, but even indices that are less than 2.5 can cause significant cardiopulmonary impairment. Defects with an index of more than 3.2 are usually considered for repair, as this is generally considered the cutoff between mild and moderate pectus excavatum.

## TREATMENT

Some nonoperative measures aimed at decreasing the patient's symptoms exist, but they are generally only minimally effective. Patients can be taught to increase breathing efforts to increase diaphragmatic excursion, allowing for increased oxygen exchange. Improvement in posture, either through conscious efforts to straighten posture or with the help of support vests, can improve air exchange. External braces can help correct posture, but these have been largely associated with only minimal correction of the deformity.

A relatively new alternative to surgery is the vacuum bell. It consists of a bowl-shaped device which fits over the sternal concavity; the air is then removed by the use of a hand pump. The vacuum created lifts the sternum upwards, lessening the severity of the deformity. As this procedure is a recent development, there is currently no information as to whether it is effective in the long term. Nonetheless, some authorities advocate the use of this continuous external vacuum as another alternative to surgical therapy in patients with mild Haller scores who want correction for cosmesis.

Other cosmetic options include the use of bioprosthetics to fill the concavity. Dermal fillers such as polyalkylimide have been used with acceptable cosmetic results. Solid silicone implants have been used for many years as well, and more recently polyethylene implants have been inserted subcutaneously. While these do nothing for the physiologic complications of pectus excavatum, they can significantly alleviate the psychosocial effects and may be considered for patients with mild deformities and no physiologic impairments, or those who are poor surgical candidates.

Surgical repair of pectus excavatum should be performed in patients with cardiopulmonary impairment, pain, or concerns about cosmesis resulting in poor body image. A recent multicenter study has demonstrated that children who underwent corrective surgery for pectus excavatum had significant improvement in lung function and  $\text{VO}_2$  max. Although the best time for repair is uncertain, children ideally

should undergo surgical repair between the ages of 12 and 18 years, when they are old enough to understand the nature, consequences, and magnitude of the surgery. This awareness includes the knowledge of the level of pain that might be experienced postoperatively, and the temporary limitation of activity. Although the surgery can be performed when the child is older than 18 years, it should not be delayed too long so as to take advantage of the pliable chest wall of the growing adolescent and effect the greatest change on chest contour.

Two primary methods of surgical repair exist for pectus excavatum. Previously, the standard repair had been the Ravitch technique, introduced by Dr. Ravitch in 1949. Despite its extensive nature, this repair has been associated with good long-term outcomes, although it is now used less often than the Nuss technique except in older patients where the sternum has calcified, when the deformity is complex and asymmetrical, or when the less-invasive Nuss procedure has been unsuccessful. The Nuss repair, developed in 1987, has been associated with equivalent cosmetic results to those from the open Ravitch repair, and the procedure may be more cost-effective because it has a shorter operating time. Both procedures have a bar placed during the procedure. In the Ravitch procedure, the bar is removed after 6 months. In the Nuss repair, the bar remains in place for 2 to 3 years in children to allow for permanent remodeling of the costal cartilage. This process is slower in the older patient because of the decrease in growth; thus, in the Nuss repair in adults, the bar remains for 3 to 5 years. The bar is removed as an outpatient procedure, although some patients elect to keep the bars permanently so as to reduce the risk of pectus excavatum recurrence.

Adequate analgesia is typically the most troublesome problem for either procedure in the postoperative period, although it tends to be slightly more significant in the Nuss repair. Use of an epidural patient-controlled analgesia catheter greatly reduces pain after the procedure. Generally, the epidural catheter is required for several days, representing the main reason the patient remains in the hospital.

Recently, a third surgical option has been approved for testing by the FDA. The magnetic minimover procedure (3MP) uses 2 magnets, 1 inside the chest and the other on a vest worn outside the chest, which create a magnetic force field that applies a controlled sustained force. The goal is to promote movement of the rib cartilage to a more normal position, resulting in a more gradual correction of the chest wall over a period of months using nominal force. Advantages of the procedure over Ravitch or Nuss procedures include significantly improved pain control, decreased length of hospital stay, lack of postoperative activity restrictions, and the ability to perform additional corrections without requiring additional operations. Disadvantages include risk of interference with surrounding implantable devices such as pacemakers if within 6 inches of the device, ineligibility for MRI scanning, and occasionally attracting metal objects in the immediate environment, as well as the fact that this procedure results in

gradual correction over several months versus the relatively immediate results of the more invasive operations. Because the vest must be worn every day for a long period of time, patient adherence is likely to be the most significant difficulty with this approach. Additionally, results are best when used on young children typically younger than 12 years, and the treatment is less effective in older children once a significant amount of cartilage has been replaced with less pliable bone. Moreover, the placement of the magnet requires an incision in the anterior chest, which still leaves a scar, thus minimizing the cosmetic benefit compared to surgical repair. No long-term data exist, since the procedure is currently in testing at the University of California–San Francisco, the University of California–Davis, and Shriners Hospital of Sacramento.

## PROGNOSIS

Long-term outcomes have shown both Ravitch and Nuss types of repair to be effective. Research shows that 97% of patients undergoing the Ravitch procedure express very good or excellent results, with similar satisfaction reported for the Nuss procedure. Symptoms of pain and decreased exercise intolerance that are present before surgery generally improve afterwards. Many asymptomatic patients who have a normal preoperative pulmonary function test and cardiac echo report significant improvement in their exercise tolerance and endurance, although they had not realized they had had any limitations before surgery.

Complications with the Ravitch repair method include impaired chest wall growth with possible constriction of the thorax from inability of the thorax to develop after surgery, abnormal cartilage regrowth and scarring, chest wall defects from failure of cartilage regrowth, pneumothorax, and denervation of the sternum. The most common complication with the Nuss repair method is displacement of the bar, but modifications in the technique and increased surgeon experience have led to low rates of bar migration. Life-threatening complications include cardiac, vascular, and lung injuries, which are rare but are reported in the literature. These typically occur with blind passage of the pectus bar across the chest, and thus this technique should be avoided. No cases of cardiac perforation have occurred with the use of thoracoscopy during the procedure. A large meta-analysis evaluating the differences between the 2 procedures noted no differences with respect to overall complications, length of hospital stay, and time to ambulation. However, the rate of reoperation was higher with the Nuss procedure because of bar migration or persistent deformity. Also, postoperative hemothorax and pneumothorax after the Nuss procedure were higher compared to the Ravitch procedure, as were pain scores while in hospital. The Ravitch procedure showed an increased intraoperative time and a significantly longer period of activity restriction compared to the Nuss procedure, as well as permanent anesthesia over the sternum. No studies showed a significant difference in patient satisfaction.

The advent of a minimally invasive technique to repair pectus excavatum has changed the approach to patients with this deformity. Children who previously lived with psychosocial issues because of poor body image or physical limitations (or both) can now undergo a safe and effective operation with minimal morbidity. The breadth of patients who are referred for surgical repair is likely to widen, and more patients should be able to undergo a secure and dependable elimination of the defect. Results of a multicenter study have demonstrated that the minimally invasive technique is safe and effective in providing functional as well as cosmetic improvement.

## PECTUS CARINATUM

Pectus carinatum is the second most common chest wall abnormality. While excavatum deformities account for approximately 90% of chest wall defects, pectus carinatum comprises less than 5%. It is characterized by a protuberance of the sternum that mimics a pigeon's chest. It is usually a symmetric, midline deformity and is seldom associated with cardiovascular compromise. Most commonly, the open Ravitch repair method for pectus excavatum is performed to correct the deformity. Thoracoscopic techniques are also used to repair this defect. Some investigators have advocated the use of conservative measures, such as external braces applying constant pressure, as an alternative to surgical repair. These have proven to be effective in the treatment of the condition in patients younger than 16 years of age. Similarly to the magnetic vest treatment of pectus excavatum, the most common cause of treatment failure when used in the appropriate age group is lack of adherence. In addition, minimally open variations of the Ravitch repair have been described for both the excavatum and carinatum deformities.

## Chapter 310

# PERTUSSIS (WHOOING COUGH)

Camilla Sabella, MD

## DEFINITIONS

Pertussis (whooping cough) is a highly contagious, bacterial respiratory infection caused by *Bordetella pertussis*, an aerobic gram-negative coccobacillus. The illness is characterized by spasms of intense coughing and a protracted clinical course lasting several weeks. A characteristic severe, paroxysmal cough ending in the inspiratory *whoop* is most often seen in infants and young children, who experience the most severe manifestations of this illness.

## EPIDEMIOLOGIC FEATURES

Worldwide, pertussis is an important killer of children, with an estimated 300,000 pertussis-related deaths annually. Before the availability of whole-cell pertussis vaccines in the late 1940s, pertussis was a major cause of morbidity and mortality in the United States, accounting for almost 300,000 cases and 10,000 deaths annually. Cases significantly decreased after an effective vaccine was introduced—the incidence declined by 99% (compared with the prevaccine era) in the early 1970s, with a record low of 1,010 cases in 1976 (Figure 310-1). However, the incidence of pertussis in the United States has steadily increased since the early 1980s (Figure 310-2). Although the disease is endemic, with all 50 US states reporting cases annually, epidemic peaks occur every 3 to 5 years, and several large outbreaks in North America have been reported in the last several years. These outbreaks have occurred in both highly immunized populations and in infants who had not received 3 doses of the vaccine. In 2004, 25,827 cases were reported in the United States, marking the highest number of cases

**Figure 310-1** Pertussis: United States, 1940–2012. (From Centers for Disease Control and Prevention. Available at: [www.cdc.gov/vaccines/pubs/pinkbook/pert.html](http://www.cdc.gov/vaccines/pubs/pinkbook/pert.html). Accessed September 25, 2015.)

**Figure 310-2** Pertussis: United States, 1980–2012. (From Centers for Disease Control and Prevention. Available at: [www.cdc.gov/vaccines/pubs/pinkbook/pert.html](http://www.cdc.gov/vaccines/pubs/pinkbook/pert.html). Accessed September 25, 2015.)

reported since 1959. In 2010, 27,550 cases and 27 pertussis-related deaths were reported.

During the last several decades, the age distribution of pertussis changed significantly. In the prevaccine era, the peak incidence of disease occurred in children aged 1 to 5 years. With widespread vaccination and by the late 1980s, infants younger than 1 year had the highest age-specific incidence, which declined with increasing age. However, since the early 1990s, a marked increase has occurred in reported cases in children aged 10 years and older. Data from the National Notifiable Diseases Surveillance System reveal that children aged 10 to 19 years comprised 33% of all reported cases between 2001 and 2003, whereas 23% of cases occurred in individuals aged 20 years and older. During the same period, infants younger than 1 year comprised 23% of all cases. From 2004 to 2005, approximately 60% of reported cases were among those 11 years of age and older, but infants younger than 1 year of age continue to have the highest average annual incidence. However, the overall number of pertussis cases is likely underestimated because the infection is often underdiagnosed in adolescents and adults.

*Bordetella pertussis* is a highly contagious organism, as demonstrated by 80% to 90% secondary attack rates among susceptible household contacts. The organism is acquired through direct transmission from close respiratory contact. Most cases in the United States occur between the months of June and October. Although chronic carriage of the organism does not occur, subclinical or mild illness commonly occurs in fully or partially immunized, as well as naturally immune, individuals. This proclivity occurs because immunity wanes within 3 to 5 years of vaccination or natural infection and is often undetectable at 12 years. Thus, neither vaccination nor natural disease provides long-lasting immunity, and adults in this country do not have adequate protection against pertussis. Importantly, adults and adolescents with pertussis serve as important reservoirs for infection and often serve as the index cases for younger infants and children. An

example of this circumstance occurred during the Chicago outbreak of 1993 where mothers served as an important source of pertussis for their infants.

Many studies prove that pertussis is a very common cause of prolonged cough in adolescents and adults, accounting for 12% to 32% of cases of cough lasting 2 weeks or longer. A prospective, US population-based study with active surveillance revealed that 13% of study participants between the ages of 10 and 49 years who visited their community clinic with an acute paroxysmal cough or a persistent cough illness of more than 2 weeks' duration had evidence of an acute pertussis infection. A Canadian study, the largest prospective study examining the rates of pertussis disease in adolescents and adults, demonstrated that 20% of 442 adolescents and adults with cough illness lasting 7 to 56 days' duration were diagnosed with pertussis.

## DIFFERENTIAL DIAGNOSIS

In infants, the differential diagnosis of pertussis includes respiratory viral illnesses, infection with *Chlamydia trachomatis* and with other *Bordetella* species, bacterial pneumonia, foreign body aspiration, and reactive airway disease.

### Adenovirus

Adenovirus can produce a clinical syndrome of prolonged paroxysmal cough, post-tussive emesis, and inspiratory whoop, which can be indistinguishable from pertussis. The presence of associated features commonly found with adenovirus, such as pharyngitis and conjunctivitis, can help distinguish clinically between these entities.

### Respiratory Syncytial Virus

Respiratory syncytial virus (RSV) is a common cause of upper and lower respiratory tract infection in neonates and infants and can occasionally be difficult to distinguish from pertussis. In addition, dual infection with RSV and *B. pertussis* can occur, and apnea is a common complication of both infections. The presence of predominantly lower respiratory tract signs (wheezing), fever, and ongoing symptoms between cough episodes is more suggestive of RSV infection than pertussis.

### *Chlamydia trachomatis*

*Chlamydia trachomatis*, a common cause of afebrile pneumonia in young infants, can mimic pertussis. However, infants with chlamydial infection usually have a staccato rather than paroxysmal cough, lower respiratory tract signs such as tachypnea and rales, and often a history of conjunctivitis in the neonatal period.

### Other *Bordetella* Species

*Bordetella parapertussis* and, rarely, *Bordetella bronchiseptica* are associated with a pertussis-like illness but characteristically cause a less protracted illness.

### Bacterial pneumonia

Bacterial pneumonia caused by *Staphylococcus aureus* and *Streptococcus pneumoniae* is not difficult to distinguish from pertussis based on the clinical manifestations

(high temperature, ill appearance, respiratory distress). However, these agents can secondarily complicate pertussis infection.

The differential diagnosis of pertussis in the older child, adolescent, and adult includes adenoviral infection, infection with *Mycoplasma pneumoniae* and *Chlamydophila pneumoniae*, asthma, and upper respiratory tract infection. *M pneumoniae* is a common cause of prolonged cough and may be difficult to distinguish from pertussis. Concurrent outbreaks have been reported. The presence of systemic symptoms, such as headache, sore throat, rales on auscultation of the chest, and a chest radiograph image that characteristically seems worse than the appearance of the child, all favor the diagnosis of *M pneumoniae*.

## EVALUATION

A complete history is by far the most important aspect of the evaluation of the infant or child with possible pertussis. A clinical diagnosis of pertussis can be made based on this history and may be supplemented by information gathered from the physical examination, as well as laboratory and radiographic information. However, because the physical examination is usually normal, the diagnosis may be missed if attention is not paid to the historical description of the coughing paroxysms. Because of the high morbidity and mortality rates associated with neonatal and infant pertussis, any young infant who has a history of cough paroxysms should have these paroxysms witnessed by a medical professional before a disposition is planned.

### Clinical Features in Infants and Children

After a usual incubation period of 7 to 10 days (range, 5–21 days), the catarrhal phase consists of nonspecific upper respiratory tract infection symptoms with rhinorrhea, lacrimation, mild cough, and conjunctival injection. This phase is followed by the paroxysmal stage, which is characterized by an intermittent dry, hacking cough. In this stage, a repetitive series of forceful coughs within a single expiration occur. A sudden, massive inspiratory respiratory effort often occurs at the end of the cough paroxysm, resulting in a high-pitched *whoop*. Between the attacks, the child seems comfortable without apparent distress. The paroxysmal stage in very young infants often lacks the characteristic *whoop* and is characterized by episodes of gagging, gasping, apnea, bradycardia, and cyanosis. Video clips of infants with pertussis can be found at [www.vaccineinformation.org/video/pertussis.asp](http://www.vaccineinformation.org/video/pertussis.asp). The *convalescent* stage is characterized by diminishing severity and frequency of paroxysms. However, patients with pertussis commonly continue experiencing intermittent coughing for weeks to months, which are often exacerbated by subsequent intercurrent respiratory illness.

Physical examination of children with pertussis is usually normal, except that they may have conjunctival hemorrhage and upper body petechial lesions, evidence of the forcefulness of their cough and posttussive emesis. Fever is characteristically absent at all stages and, if present, should immediately suggest

secondary bacterial infection. Leukocytosis caused by absolute lymphocytosis is a common finding in unimmunized infants and children who are in the paroxysmal or late catarrhal stage of pertussis. The degree of lymphocytosis parallels the severity of disease. Chest radiography is commonly normal but may reveal perihilar infiltrates, pneumothorax, or pneumomediastinum.

### Clinical Features in Adolescents and Adults

Pertussis in adolescents and adults does not usually have distinct phases. A persistent (>21 days) cough, which is indistinguishable from other respiratory infections, can be the only symptom. However, a paroxysmal nature to the cough is present in approximately 70% to 99% of infected individuals. Other features include inspiratory whoop, posttussive emesis, choking, and sleep disturbed by cough. Positive predictors of confirmed pertussis infection include a history of prolonged duration of violent cough (median, 43 days), a longer duration of cough illness (median, 56 days), and posttussive emesis. Posttussive emesis is common at all ages and serves as a clue to the diagnosis in older children and adults.

Similar to infants and children, adults with pertussis do not have fever. Unlike in infants, leukocytosis and lymphocytosis are not common in adults and in partially immunized children with pertussis.

### Diagnosis

Definitive diagnosis of pertussis is problematic. Culture and polymerase chain reaction (PCR) testing of nasopharyngeal secretions are insensitive modes of diagnosis, whereas serologic testing is sensitive but impractical.

### Culture

Isolation of the organism by culture remains the diagnostic standard, but, because of the fastidious nature of the organism, is highly dependent on appropriate specimen collection, specimen transport, and isolation technique. Appropriate culture is obtained from the posterior nasopharynx using a calcium alginate or Dacron-tipped (not cotton) swab. The specimen should then be immediately inoculated onto Regan-Lowe medium and incubated for 7 days. A semisolid transport media is available if the specimen cannot be immediately inoculated onto solid media. Even when ideal conditions are met, the sensitivity of culture is suboptimal because cultures are most likely to be positive early in the illness (catarrhal and early paroxysmal phase) in unimmunized children. Culture sensitivity is greatly diminished when obtained late in the illness, in immunized individuals, and in those who received macrolides or sulfonamides.

### Polymerase Chain Reaction Testing

Polymerase chain reaction testing of nasopharyngeal specimens is more widely available and increasingly used to diagnose pertussis. The PCR test is more sensitive than culture, including in individuals who are mildly symptomatic and in those who were treated with macrolides. The sensitivity of PCR when compared with serologic tests that are used for research purposes

is highly dependent on the child's age (60%–70% sensitive in infants and young children but <10% sensitive in older children and adults), which likely reflects past immunization and immune responses. High rates of false-positive results have been reported from some laboratories, and there is no standardized protocol for the *B pertussis* PCR test. Polymerase chain reaction can detect *B paraptussis* as well.

### Direct Fluorescent Antibody Testing

Direct fluorescent antibody testing of nasopharyngeal specimens for pertussis antigens was used in the past but was plagued by poor sensitivity when compared with culture and required experienced laboratories for accurate results. This test is no longer recommended.

### Serologic Testing

Serologic testing for the detection of antibodies to components of *B pertussis* in acute and convalescent samples is the most sensitive mode of diagnosis. These tests have been used extensively in epidemiologic studies and vaccine trials and have enabled an understanding of the role of pertussis in adolescents and adults with prolonged cough illness. However, the results from these tests are difficult to interpret in immunized individuals, cutoff points are not available for diagnostic values, and these tests are not licensed for diagnostic use.

### Complications of Pertussis

Young infants have the highest incidence of morbidity and mortality with 91% of pertussis-related deaths occurring in children younger than 6 months. Secondary bacterial pneumonia is the most common complication, occurring in approximately 5% of all reported cases, and is the cause of most pertussis-related deaths. Infants younger than 6 months have the highest rate of hospitalization (69%), secondary bacterial pneumonia (13%), and seizures (2%). Other important complications include apnea, bradycardia, dehydration, pulmonary hypertension, pneumothorax, central nervous system changes, and retinal hemorrhages. Although complications are much more common in infants, pertussis causes significant morbidity in

adults, including pneumonia, otitis media, sinusitis, rib fracture, pneumothorax, pneumomediastinum, weight loss, and urinary incontinence.

## MANAGEMENT

### Supportive Care

Supportive care continues to be the mainstay of managing pertussis infections. Hospitalization is indicated for most infants younger than 6 months to assess for life-threatening events associated with paroxysms, such as apnea, bradycardia, and hypoxia. Hospitalization also provides continuous cardiopulmonary monitoring, vigilant nasopharynx suctioning, oxygen therapy (if needed), careful attention to feeding and hydration, and monitoring and treating acute complications.

### Antibiotics

A macrolide antibiotic is indicated for proven or suspected pertussis to eliminate the organism from the nasopharynx and thus limit the spread to others. If administered early in the illness, this therapy can reduce the duration and severity of symptoms. However, these agents have little influence on the clinical course of pertussis unless their use is started early in the catarrhal phase of the illness.

The macrolides azithromycin, erythromycin, and clarithromycin are the drugs of choice for treating pertussis infection (Table 310-1). The newer macrolide agents, clarithromycin and azithromycin, are as effective as erythromycin for treating pertussis, are better tolerated, and are associated with fewer and milder adverse effects than erythromycin. Although azithromycin and clarithromycin are not approved by the US Food and Drug Administration for infants younger than 6 months, their use is encouraged based on their *in vitro* effectiveness, demonstrated safety in older infants and children, and more convenient dosing schedule. Although both erythromycin and azithromycin therapy are associated with infantile hypertrophic pyloric stenosis (IHPS), azithromycin is currently the preferred macrolide in infants younger than 1 month because the risk of IHPS is thought to be less. All infants younger than 1 month who receive any macrolide should be monitored for

**Table 310-1**

**Antimicrobial Treatment and Postexposure Prophylaxis for Pertussis by Age Group**

AGE GROUP	RECOMMENDED AGENT
<1 mo	Azithromycin 10 mg/kg/day as single daily dose for 5 days
1–5 mo	Azithromycin 10 mg/kg/day as single daily dose for 5 days, OR erythromycin 40–50 mg/kg/day in 4 divided doses for 14 days, OR clarithromycin 15 mg/kg/day in 2 divided doses for 7 days
Infants ≥6 mo and children	Azithromycin 10 mg/kg/day as single dose on day 1, then 5 mg/kg/day (maximum 500 mg) on days 2–5, OR erythromycin 40–50 mg/kg/day (maximum 2 g/day) in 4 divided doses for 14 days, OR clarithromycin 15 mg/kg/day in 2 divided doses (maximum 1 g/day) for 7 days
Adolescents and adults	Azithromycin 500 mg as single daily dose on day 1, then 250 mg/day on days 2–5, OR erythromycin 2 g/day in 4 divided doses for 14 days, OR clarithromycin 1 g/day in 2 divided doses for 7 days

Adapted from Centers for Disease Control and Prevention. Recommended antimicrobial agents for the treatment and postexposure prophylaxis of pertussis. 2005 CDC guidelines. *MMWR*. 2005;54(RR14):1–16.

IHPS during and for 1 month after completing the course of therapy.

Trimethoprim-sulfamethoxazole (TMP-SMX) is the recommended alternative for children older than 2 months who cannot tolerate macrolides. The dosing regimen for TMP-SMX is:

- 2 months of age or older: TMP, 8 mg/kg/day; SMX, 40 mg/kg/day in 2 doses for 14 days
- Adolescents and adults: TMP, 320 mg/day; SMX, 1,600 mg/day in 2 divided doses for 14 days

The treatment for *B. parapertussis* is the same as for *B. pertussis*.

### Care of Household and Other Close Contacts

Because of the high transmission rate from infected to susceptible individuals and proven efficacy of chemoprophylaxis, a macrolide should be given promptly to all household and close contacts (eg, those in child care) of infected individuals. Chemoprophylaxis significantly reduces but does not eliminate the risk of pertussis. Because immunization may not always prevent infection, chemoprophylaxis should be given to close contacts regardless of age and immunization status. Health care workers who have a definite or likely exposure to pertussis should also receive chemoprophylaxis. The antimicrobial agents that should be used for postexposure prophylaxis are the same as for treatment of pertussis (see Table 310-1). Trimethoprim-sulfamethoxazole is an alternative prophylactic option for children who cannot tolerate macrolides; however, this antibiotic is contraindicated in infants younger than 2 months.

### Prevention

Universal immunization with pertussis vaccines for children younger than 7 years is recommended by the American Academy of Pediatrics (AAP) and is the mainstay of prevention. Vaccination of all children starting in infancy decreased the incidence of pertussis in the United States by more than 97%, compared to the prevaccine era. The currently available acellular vaccines, which are purified subunit vaccines and combination vaccines with diphtheria and tetanus toxoids (diphtheria-tetanus-acellular pertussis [DTaP]), have been shown to be 75% to 90% effective and are well-tolerated. The AAP recommends that a total of 5 doses of pertussis vaccine be administered to every child before school entry, unless contraindicated. The first dose is given at 2 months of age and is followed by 2 subsequent doses at intervals of 2 months. A fourth and fifth dose are recommended at 15 to 18 months of age and at 4 to 6 years of age, respectively. Children between 7 and 10 years of age who have not completed their primary immunization schedule or have an unknown vaccine history should receive a single dose of Tdap.

Despite the successes of universal immunization, reported cases of pertussis in this country are steadily increasing, with resultant significant morbidity and mortality. This increase seems to be because waning immunity occurs after vaccination and natural infection, mild disease is underdiagnosed, and infants who do not complete their primary immunization series remain susceptible to infection.

Because of the role that adolescents and adults play in pertussis transmission, much interest has been

### BOX 310-1 American Academy of Pediatrics Recommendations for Use of Tetanus and Diphtheria Toxoids and Acellular Pertussis (Tdap) Vaccines in Adolescents

- Single dose of Tdap instead of tetanus and diphtheria toxoids (Td) vaccine for booster immunization for adolescents 11 to 18 years of age.
- The preferred age for Tdap immunization is 11 to 12 years.
- Adolescents 11 to 18 years of age who have received Td but not Tdap are encouraged to receive a single dose of Tdap. An interval of 2 years between Td and Tdap immunization is suggested. However, Tdap can be given at shorter intervals in settings of increased risk of pertussis, such as for a close contact with a case, outbreak setting, and close contact with an infant.

Adapted from American Academy of Pediatrics. Pertussis (whooping cough). In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015:608–621.

generated in studies evaluating the efficacy and safety of pertussis vaccination in these age groups. Traditionally, pertussis vaccine was not recommended for children aged 7 years and older because of past concerns about the safety of the previously used whole-cell vaccines in this age group. However, adverse reactions to the acellular pertussis vaccines among adolescents and adults are mild, with local swelling and redness most commonly reported. A National Institutes of Health–sponsored prospective multicenter trial, in which 2,781 healthy subjects aged 15 to 65 years were randomized to receive acellular pertussis vaccine or hepatitis A vaccine, found that the acellular pertussis vaccine is safe, immunogenic, and effective in preventing clinical pertussis.

Given the immunogenicity and safety of these vaccines in adolescents and adults, the AAP recommends that adolescents aged 11 to 18 years receive the Tdap vaccine (Box 310-1). It is also reasonable to recommend to parents that they consider getting vaccinated as a means of preventing spread to their children.

### WHEN TO ADMIT

- Strongly consider in any infant younger than 6 months suspected of having pertussis.
- When complications, such as apnea, bacterial pneumonia, bradycardia, or pulmonary hypertension, exist.
- When the infant has an oxygen requirement or when the infection is interfering with feeding.

## Chapter 311

# PHARYNGITIS AND TONSILLITIS

Russell W. Steele, MD

### INTRODUCTION

Acute pharyngitis is one of the more common diagnoses made in pediatric practice, exceeded only by otitis media and viral upper respiratory tract infections. It is also the most common diagnosis requiring treatment with antibiotics in school-aged children.

### DEFINITIONS

The term *pharyngitis* implies inflammation of the throat with or without the presence of exudate; when the tonsils are affected, the terms *tonsillitis*, *tonsillopharyngitis*, and *pharyngotonsillitis* are more commonly used. Pharyngitis may be associated with other inflammatory conditions of the mucous membranes (eg, herpes gingivostomatitis, herpangina, Stevens-Johnson syndrome, Kawasaki disease), or it may be the sole finding in an illness. Generally, a clinical complaint of sore throat indicates some degree of pharyngitis.

### ETIOLOGY

Although pharyngitis is most commonly caused by viral agents, the major management step is to establish whether group A  $\beta$ -hemolytic *Streptococcus* (GABHS) is the responsible pathogen, because the presence of GABHS mandates early antimicrobial therapy within 9 days of onset of symptoms to eradicate this bacterium and thereby prevent acute rheumatic fever. In children younger than 3 years, GABHS is the cause of tonsillopharyngitis in less than 3% of cases, whereas in children older than 3 years, estimates suggest that 15% to 20% of pharyngitis episodes are caused by GABHS. The reason for the low incidence in young children is that their pharyngeal mucosal cells have fewer receptors for GABHS. The cause of pharyngitis varies somewhat depending on the geographic location and season, particularly during recognized outbreaks of GABHS, influenza, respiratory syncytial virus, and mycoplasma. In addition to these causes, many other infectious agents have been associated with pharyngitis (Box 311-1).

### Viruses

Although many primary care physicians associate pharyngitis and tonsillitis with bacterial pathogens, viruses play a major role in the cause of these illnesses. Moreover, when pharyngitis is associated with upper respiratory tract symptoms, such as conjunctivitis, nasal congestion, and rhinorrhea, GABHS and other bacterial agents are highly unlikely causes.

### Adenoviruses

At least 12 different types of adenoviruses have been found to cause pharyngitis in children and adolescents, accounting for up to 23% of cases in some reports. These viruses cause both a nasopharyngitis and a tonsillitis that can be exudative. Outbreaks of a unique clinical illness caused by adenovirus types 3, 7, 2, 4, 7a, 11, and

### BOX 311-1 Causes of Pharyngitis

#### BACTERIA

- *Streptococcus pyogenes*
- *Corynebacterium diphtheriae*
- *Arcanobacterium hemolyticum*
- *Neisseria gonorrhoeae*
- Group C streptococci
- Group G streptococci
- *Chlamydia pneumoniae*
- *Chlamydia trachomatis*
- *Mycoplasma pneumoniae*
- *Yersinia enterocolitica*
- *Francisella tularensis*
- *Coxiella burnetii*

#### VIRUSES

- Epstein-Barr virus
- Adenovirus
- Enteroviruses
- Herpes simplex viruses
- Influenza
- Parainfluenza
- Rhinoviruses
- Coronavirus
- Human metapneumovirus
- Human bocavirus
- Respiratory syncytial virus

14, called pharyngoconjunctival fever because of these consistent features, occur frequently. Affected patients may also have cough, myalgias, and conjunctivitis.

### Enteroviruses

Three prominent members of the enterovirus class of viruses, coxsackieviruses A and B and echovirus, have been shown to cause pharyngitis, often accompanied by respiratory symptoms, commonly in the late summer or early fall. Herpangina is a specific entity caused by various strains of coxsackieviruses A and B, typified by pharyngitis associated with small, shallow, erythematous, ulcerated areas on the soft palate and peritonsillar area.

### Epstein-Barr Virus

Epstein-Barr virus (EBV) is an etiologic agent of infectious mononucleosis that frequently causes a severe exudative pharyngitis with a characteristic white, shaggy membrane on the tonsils and palatal petechiae. In older children, EBV infection is frequently accompanied by fever, adenopathy, malaise, swelling of the eyelids, a generalized rash, and hepatosplenomegaly. EBV is a copathogen of GABHS in 5% to 10% of cases.

### Herpes Simplex Virus

Although most oral colonization and covert infection with herpes simplex virus type 1 is asymptomatic, this virus can cause painful gingivostomatitis and pharyngitis in approximately 1% of infected children. Studies in a college-aged population have also documented that herpes simplex virus types 1 and 2 account for 5.7% of pharyngitis cases.

### Other Viruses

Many other viruses cause pharyngitis, although pharyngitis is usually not the primary manifestation of the illness. These viruses include influenza, parainfluenza, respiratory syncytial virus, human metapneumovirus, human bocavirus, measles, coronavirus, and rhinoviruses.

### Bacteria

One of the main considerations in evaluating a child who has pharyngitis and tonsillitis is to determine whether the cause is bacterial, thus requiring specific antibiotic therapy. GABHS infections are the major bacterial cause, but other organisms should be considered in certain situations.

### *Streptococcus pyogenes*

*Streptococcus pyogenes* causes complete ( $\beta$ ) hemolysis when grown on blood agar and hence has been called  $\beta$ -hemolytic *Streptococcus*. Streptococci have been subdivided into groups based on the C-substance in the cell wall, and most human pathologic disease has been found to be caused by the A group. GABHS was not fully recognized as a frequent cause of pharyngitis with the possibility of subsequent rheumatic fever until the 1940s. Whereas other groups of *Streptococcus* (B, C, F, and G) have been associated at times with pharyngitis, GABHS is by far the most frequent bacterial cause. GABHS can be divided into M and T serotypes, and a certain number of these serotypes have been associated with both the rash of scarlet fever

(GABHS T4) and the development of rheumatic fever (GABHS M3 and M18).

The pharyngitis caused by GABHS characteristically begins after a 2- to 5-day incubation period, usually after exposure to another individual who has the infection. Spread is thought to occur by way of respiratory secretions, although fomites, such as shared silverware or household cats (but not dogs), have occasionally been shown to be vectors. The ingestion of GABHS-contaminated food also has led to outbreaks of pharyngitis. The illness is heralded by sudden onset of fever, sore throat, and dysphagia, often associated with headache and abdominal pain. Examination of the throat reveals an erythematous pharynx and tonsillar area, often with exudate present. Small petechiae (enanthem) are sometimes seen on the uvula and soft palate. Cervical lymph nodes are usually enlarged and tender. These symptoms can last 4 to 5 days, gradually subsiding when no antibiotic therapy is instituted. Penicillin therapy shortens the duration of fever and sore throat by 1 to 1½ days and, if given within 9 days of onset, prevents rheumatic fever.

Key findings include

1. Red throat or tonsils and/or exudative tonsils
2. Swollen and usually tender anterior cervical nodes
3. Fever
4. Scarlet fever rash

### *Neisseria gonorrhoeae*

Pharyngitis in sexually active adolescents or sexually abused children can be caused by *Neisseria gonorrhoeae* acquired from oral sex, and the organism should be sought when appropriate. Exudative tonsillitis is rarely seen with pharyngitis caused by *N gonorrhoeae*.

### *Haemophilus influenzae* Type b

The possible involvement of the *Haemophilus influenzae* type b (Hib) organism in pharyngitis and tonsillitis has been controversial, but evidence suggests that it may contribute to infection in some children, especially those with recurrent tonsillitis. Fine-needle aspiration of tonsils during acute tonsillitis and pathologic specimens from tonsillectomy have documented that as many as 20% of sampled tonsils have Hib infection. However, with Hib immunization of most infants in the United States in recent years, this organism may be less likely to play a role in the pathogenesis of acute tonsillitis and pharyngitis.

### Lemierre Syndrome

This infection caused primarily by the anaerobic bacterium, *Fusobacterium necroforum*, begins as severe tonsillopharyngitis in previously healthy adolescents and young adults. It then progresses to septic thrombophlebitis of the internal or external jugular veins and subsequent severe pulmonary infection. Additional clinical features include fever  $>39^{\circ}\text{C}$  ( $102.2^{\circ}\text{F}$ ), respiratory distress, and unilateral neck swelling or pain.

### *Arcanobacterium hemolyticum*

Approximately 7% of tonsillopharyngitis in adolescents and young adults is caused by *Arcanobacterium*

*hemolyticum*. Physical findings are identical to those seen with GABHS infection, including a scarlatiniform rash present in approximately 20% of cases. The sore throat may persist until patients are treated with erythromycin, azithromycin, or clarithromycin.

### Other Bacteria

A century ago, *Corynebacterium diphtheriae* was a frequent and deadly cause of pharyngitis, with a characteristic gray pseudomembranous exudate over the posterior pharynx and tonsils. Fortunately, *C diphtheriae* now is rare in North America, although it is still being reported in some developing countries. Various reports have been published of other bacteria causing pharyngitis and tonsillitis, including *Actinomyces*, *Chlamydia trachomatis* and *Chlamydia pneumoniae*, *Yersinia enterocolitica*, *Coxiella burnetii*, and *Francisella tularensis* (oropharyngeal tularemia).

### Other Causes

#### *Mycoplasma pneumoniae*

Two types of *Mycoplasma pneumoniae* have been shown to cause pharyngitis, namely *M pneumoniae* and *M hominis*. In children, the former causes a mild pharyngitis, often associated with a laryngotracheitis or progressing to bronchitis or pneumonia. In school-aged children, as much as 5% of pharyngitis may be caused by this organism.

#### Fungi

*Candida* infection is an uncommon cause of pharyngitis in the healthy host but can certainly be seen in immunocompromised patients or those taking steroids. With oral thrush in otherwise healthy children, severe mouth pain can occur, which may be interpreted as a sore throat.

#### Kawasaki Disease

Of unknown cause, Kawasaki disease occurs mostly in preschool-aged children who have pharyngitis associated with erythema and fissuring of the lips as well as palmar and pedal edema and erythema. An association with staphylococcal toxin has been postulated, as have other viral and bacterial etiologies. (See Chapter 280, Kawasaki Disease.)

#### Exposure to Cigarette Smoke

Although smoke itself has not been reported to cause pharyngitis or tonsillitis, a highly significant association has been found between the incidence of tonsillectomy in children and parental smoking. One study found children of smokers also had a much higher frequency of attacks of acute tonsillitis compared with children in a smoke-free environment. Whether this association will be confirmed in other studies remains to be seen, but among children seeking treatment for frequent tonsillitis, a history of parental smoking should be sought. If such a history exists, advising measures to reduce the child's exposure to cigarette smoke would be prudent.

## DIFFERENTIAL DIAGNOSIS

Sore throats are common in children, and almost all children older than 3 years need to be examined to rule out GABHS as the cause. If GABHS is the

documented cause, then antibiotic therapy should be instituted in an effort to prevent rheumatic fever. Unfortunately, multiple studies have shown that streptococcal pharyngitis cannot be distinguished purely on clinical grounds. Streptococcal infections should be considered in children older than 3 years who have pharyngitis, even if no exudate is present. However, pharyngitis associated with nasal, chest, or cold symptoms is much more likely to be a viral illness.

When pharyngitis is atypical, either in its duration or its severity, the physician should suspect infectious mononucleosis or one of the rarer bacterial causes, including those that are sexually transmitted. A peritonsillar abscess or cellulitis (Quinsy) also may cause a sore throat, but thorough examination will reveal swelling extending into the soft palate, with deviation of the uvula and a change in the tonal quality of the voice. Allergies may lead to chronic inflammation of the mucous membranes, which might include the pharynx, but pharyngitis would be infrequent as a sole manifestation. Postnasal drip from a viral respiratory tract infection or allergies has been thought to irritate the posterior pharynx, but this finding is not well documented.

Acute tonsillopharyngitis may progress to a peritonsillar abscess. Researchers have observed that 41% to 70% of peritonsillar abscesses occur in the superior pole. This infection begins with the typical signs and symptoms of pharyngitis such as sore throat, dysphagia, and fever, usually in an older child who often has a history of recurrent tonsillitis. Systemic symptoms such as malaise, poor appetite, and chills appear early, and mild dehydration may develop. These symptoms progress rapidly to more severe pharyngeal symptoms, such as difficulty in swallowing and speaking. The child has a toxic appearance, and trismus almost always occurs. Characteristic signs are a muffled (*hot potato*) voice, trismus, and major leukocytosis. Needle aspiration can be performed only if the abscess is within the superior pole, and the success rate with needle aspiration compares favorably with that of incision and drainage in these types of cases. Computed tomography scanning and intraoral ultrasonography are quite reliable in distinguishing abscesses from cellulitis alone. Initial antimicrobial therapy is clindamycin plus a third-generation cephalosporin such as ceftriaxone, cefotaxime, or ceftazidime. Routine tonsillectomy along with or after medical management is recommended by some experts.

The one entity in the differential diagnosis not to be missed is epiglottitis, which can be life threatening. Generally, the child who has epiglottitis has severe throat pain, rapidly becomes ill, appears to have a toxic condition, and experiences respiratory distress accompanied most often by stridor, although the child may have a croupy cough.

## MANAGEMENT

### Laboratory Procedures

#### Rapid Streptococcal Test and Cultures

The traditional method for determining whether pharyngitis or tonsillitis was caused by a virus or GABHS was to obtain a throat swab and perform a culture. Fortunately, with the availability of rapid

streptococcal tests, this process was made simpler, allowing a result to be obtained in minutes rather than waiting 1 to 2 days. Unfortunately, with the advent of strict federal guidelines for office laboratories, even the use of these rapid tests requires certification. Despite such encumbrances, most clinicians now perform a rapid streptococcal diagnostic test on all patients whose pharyngitis is suggestive of GABHS.

The various rapid streptococcal tests claim differing levels of specificity and sensitivity. They appear to be specific (95%–98%), but their sensitivity can be as low as 70% to 85%; thus, some cases of GABHS are not detected. For this reason, a positive rapid streptococcal test result is sufficient indication to treat the patient; however, if the test result is negative but a high index of suspicion exists that GABHS is the causative agent, then a culture should be sent. If little clinical evidence of pharyngitis or tonsillitis can be found in a child who complains of sore throat, or for those with manifestations highly suggestive of viral infection (coryza, conjunctivitis, cough, hoarseness, herpangina, stomatitis, Sindbis virus), a throat culture is not necessary. The physician also needs to be aware that some individuals are *Streptococcus* carriers, and they may well be found to be positive for *Streptococcus* infection during a viral illness. An asymptomatic *Streptococcus* carrier does not need to be treated, but when symptoms are present, most physicians treat these individuals, given the difficulty of being certain that GABHS is not the cause of the illness. Because performing pre- and post-illness rapid streptococcal tests or cultures on every child who presumably has GABHS pharyngitis is impractical, all those who test positive are treated.

### Serologic Tests

In cases in which EBV infection is suspected, either a heterophile antibody (Mono-spot) or specific EBV antibody test can be ordered. In older children usually a heterophile test is done in the office, and if negative the clinician may then choose to order the more sensitive EBV antibody tests. Tests of specific IgG and IgM levels of antibody to EBV viral capsid antigen (VCA) are available but are usually expensive and slow to produce results, making them less than ideal to determine the cause of an acute pharyngitis (see Chapter 275, Infectious Mononucleosis and Other Epstein-Barr Viral Infections). The EBV-VCA IgM reflects current or recent disease, while the EBV-VCA IgG indicates past infection.

Although serologic tests exist to determine recent streptococcal infections, they are rarely helpful in evaluating for acute pharyngitis. An antistreptolysin-O titer is used more commonly in diagnosing rheumatic fever by documenting a recent exposure to streptolysin with production of antibody.

### White Blood Cell Count

The only real value in performing a white blood cell count is if infectious mononucleosis is suspected. Patients who have an acute EBV infection tend to have relative lymphocytosis, with 10% to 20% atypical lymphocytes. Thus, a white blood cell count may be a helpful diagnostic study, together with a heterophile

or specific EBV antibody test, in a child who has a severe pharyngitis and is culture negative for GABHS.

### Treatment

Pharyngitis caused by viruses generally is treated symptomatically with saline gargles, throat lozenges, and analgesics such as acetaminophen. When GABHS has been documented, either by a positive rapid *Streptococcus* test or by culture, antibiotics are indicated primarily to prevent the subsequent development of rheumatic fever. Various antibiotic regimens have been used for GABHS pharyngitis or tonsillitis, but the standard therapy has been a 10-day oral course of potassium penicillin or amoxicillin given 2 or 3 times a day. Penicillin is given twice a day as 250 mg for children and 500 mg for adolescents and adults, while amoxicillin is given once a day, 50 mg/kg/day. Alternatively, intramuscular benzathine penicillin G may be given as a single injection, although these injections are often painful not only initially but also for a few days afterward. Patients allergic to penicillin may be given azithromycin for 5 days or a cephalosporin for 10 days. Although shorter courses of newer antibiotics have been studied and shown to be effective in eradicating GABHS from the pharynx, their efficacy in preventing rheumatic fever is not clear, although presumed.

Controversy exists over whether to begin antibiotics for presumptive GABHS pharyngitis while waiting for culture results. Because rheumatic fever can be prevented even if treatment is started as late as the ninth day of symptoms, the decision to begin therapy immediately rests with the individual physician, who knows the circumstances of the patient. Early antibiotic treatment will shorten the duration and severity of symptoms by 24 to 36 hours. Patients should be kept out of school and avoid close contact with family and friends for 24 hours, given that numerous studies have shown that they become culture negative after just 24 hours of antibiotic therapy.

Cephalosporins have been shown to be superior to penicillin in eradicating GABHS from the pharynx. In cases of gonococcal pharyngitis, one intramuscular injection of ceftriaxone is recommended. In young children who have this diagnosis, sexual abuse must be investigated. Other possible bacterial causes of pharyngitis are treated with appropriate antibiotics, once the causative organism has been determined (eg, azithromycin for *Arcanobacterium hemolyticum*, or streptomycin or gentamicin for oropharyngeal tularemia).

Parents often raise the question of tonsillectomy after a child has multiple episodes of pharyngitis or tonsillitis. Except in cases of documented recurrent, frequent streptococcal infection or the development of a peritonsillar abscess, tonsillectomy is not indicated in children who have recurrent pharyngitis not thought to be caused by GABHS. (See Chapter 339, Tonsillectomy and Adenoidectomy.)

Although the administration of steroids to decrease pain in acute exudative pharyngitis has been studied in adults and found to provide some benefit, the use of steroids in children is not recommended except in rare situations, such as infectious mononucleosis with imminent airway obstruction.

## COMPLICATIONS

Most cases of pharyngitis present no unusual complications because so many of them are viral and resolve with or without therapy. However, the physician must be aware of the possibility of a peritonsillar or retropharyngeal abscess or cellulitis developing and should re-examine the throat of any patient who is not improving. Other suppurative complications can also develop, such as cervical adenitis, acute otitis media, sinusitis, and pneumonia. In addition, hematogenous spread of a bacterial organism is possible and can result in bacteremia as well as joint, bone, or meningeal infection.

Rheumatic fever (see Chapter 323) is the major complication of streptococcal pharyngitis that can be life threatening, although it occurs some time after the acute throat infection. Although the incidence of rheumatic fever is low in North America, it still occurs and has been seen in increasing numbers at some centers. Although acute glomerulonephritis is possible after streptococcal throat infections, it is much more likely after streptococcal skin infections.

Some evidence has shown an association between GABHS infection and obsessive-compulsive disorders and tic behavior in children. This clinical entity is termed *pediatric autoimmune neuropsychiatric disorder associated with group A streptococcal infection* (PANDAS). Documentation is largely anecdotal but includes the observation that these children have high concentrations of antibody to streptococcal antigens. Small series have noted improvement in obsessive-compulsive disorder behavior or tics when these children are GABHS positive and treated with penicillin. However, many still question the authenticity of PANDAS.

### WHEN TO REFER

- Suspected peritonsillar abscess
- Suspected retropharyngeal abscess
- Recurrent GABHS (5 episodes in 1 year) for tonsillectomy

### WHEN TO ADMIT

- Toxic appearance (suspected toxic shock syndrome)
- Peritonsillar abscess
- Retropharyngeal abscess
- Acute rheumatic fever

## Chapter 312 PHIMOSIS

A. Barbara Oettgen, MD, MPH

Problems and questions related to the foreskin (prepuce) of young boys are relatively common among families in pediatric practices. Understanding the diagnosis and treatment of boys with foreskin problems such as phimosis, paraphimosis, and balanoposthitis is therefore important for physicians caring for children.

## PHIMOSIS

### Definition

Phimosis, or unretractile foreskin, can be both physiologic and pathologic. At birth, most boys have physiologic phimosis—the inner surface of the foreskin is developmentally fused to the glans penis. Over time, desquamation and glanular secretions allow gradual separation of the foreskin. Accumulation of smegma (the epithelial debris generated during desquamation) can sometimes be seen under the foreskin as pearls and requires no intervention. When these accumulations are eventually released, as the foreskin becomes more retractile, they may be mistaken for infection. Distinguishing pathologic phimosis from physiologic phimosis can be difficult because of the lack of clear diagnostic criteria. Probably most of the referrals made to urologists are for boys with physiologic phimosis that will resolve spontaneously over time.

Physiologic phimosis is described as an unretractile foreskin that is supple and unscarred. On attempted retraction, the foreskin lies flat against the penis and is effaced, and the tip opens as a flower (Figure 312-1). Young boys may also exhibit preputial adhesions where part of the foreskin does not completely retract, but no constricting ring is seen—this also is not pathologic and largely resolves on its own. With pathologic phimosis, the margin between the foreskin and the glans is rolled and thickened.

### Incidence

The incidence of true phimosis is probably fairly infrequent. Retractability increases yearly. By 1 year of age, 50% of uncircumcised boys have retractile foreskins, 90% by age 3, 92% by age 6 to 7, and 99% by adolescence. Smith and colleagues reported 1 case per 1,000 boys; a study in France reported a rate of 2.6% and in England 0.9%. These rates were obtained

**Figure 312-1** A, Physiologic phimosis: healthy skin at edge of prepuce. B, Pathologic phimosis: scarred ring at edge of prepuce, holding it open and showing meatus and part of glans.

after looking at pathologic specimens after circumcision. Individuals with evidence of inflammation were counted as true phimosis.

### Etiology

Pathologic phimosis is thought to have a few different causes. It can be the result of a chronic nonspecific inflammatory process or repeated infections that cause scarring and stricture. It can also be caused by forcible premature retraction of the foreskin, causing scarring and adhesions. Balanitis xerotica obliterans (BXO), a chronic dermatitis of unknown cause, histologically resembles lichen sclerosus et atrophicus and causes pathologic phimosis. Severe phimosis can also be a significant complication in boys receiving hematopoietic stem cell transplantation, especially in patients with graft-versus-host disease.

### Management

Treatment of phimosis depends on whether it is thought to be physiologic or pathologic. Watchful waiting will result in resolution of most cases of physiologic phimosis. However, if the child is thought to have pathologic phimosis, then the treatment alternatives include topical steroid cream or surgery.

#### Steroid creams

Multiple studies have investigated the use of topical steroid creams for treatment. A review of the literature in 2001 showed at least 12 studies (2 randomized controlled) in children 1 to 15 years of age. A 4- to 8-week course of therapy was found to be, on average, 85% effective. Since then, there have been a number of studies further confirming the effectiveness of steroid creams of both high and medium potency in children of all ages with varying degrees of phimosis, including those with BXO. High-potency steroid creams, such as 0.05% betamethasone, have been studied the most. However, medium-potency topical steroids (clobetasone butyrate 0.05%, fluticasone propionate 0.05%, and triamcinolone acetonide 0.1%) have also been shown to have similar resolution rates, suggesting that a lower-strength steroid may be an option. The creams are applied to the phimotic ring twice a day for 4 to 8 weeks.

Application of the steroid creams should be accompanied by gentle retraction of the foreskin. To prevent

the incidence of reoccurrence, gentle retraction of the foreskin with cleaning should continue after the steroid cream is discontinued. Steroid creams have even been used in a much younger population (1- to 31-month-old boys) who had urinary tract infections, balanitis, or genitourinary tract anomalies and were found to be successful in relieving phimosis in 92% of children. Steroids are thought to be therapeutic by decreasing any potential inflammation between the foreskin and glans and by thinning the skin, making it more supple.

Topical steroid therapy has multiple advantages over more traditional surgical management—it is less invasive and avoids the risks of surgery (bleeding, deformity, meatal stenosis) and anesthesia. It is much more cost effective, at only 25% the cost of surgery. The prepuce also may deserve preservation for social and cultural reasons, as well as the fact that it is a neurologically complex and erogenous tissue. Finally, medical therapy can prevent severe emotional problems in some boys who undergo circumcision at an older age.

### Surgery

The surgical alternatives for phimosis include dorsal slit surgery or circumcision. The dorsal slit procedure involves making a single slit dorsally in the foreskin, which mostly preserves the prepuce but allows easy retraction of the foreskin. Although the surgery is less involved and preserves the prepuce, the cosmetic result is not as satisfactory as with circumcision and can also be complicated by scarring. Families may choose this option, however, for personal or religious reasons. Circumcision is the much more commonly practiced surgery for phimosis. Beyond the neonatal period, surgery is usually done as an outpatient procedure under general anesthesia. In the postsurgical period, patients should be restricted from rough play or straddling toys for a couple of weeks. In an effort to prevent adhesion to underwear or diaper, petroleum jelly or triple antibiotic ointment should be liberally applied to the newly exposed tip until it is well healed. This will also help decrease the chance of future meatal stenosis. Forced premature retraction of the foreskin is *never* recommended and may lead to significant adhesions and scarring, as well as being painful and traumatic.

### WHEN TO TREAT

Because true phimosis can be a difficult diagnosis to establish, the choice as to which patients should be referred and receive therapy may be unclear. There are some instances for which uniform agreement exists that surgical treatment, in the form of circumcision, should be undertaken. These instances include phimosis that is resistant to steroid therapy and voiding problems. Recurrent balanitis and urinary tract infections may be other indications if topical steroid therapy is unsuccessful. Ballooning of the foreskin during micturition is, by itself, not necessarily a reason for circumcision. Using noninvasive urodynamic studies, no evidence of obstruction could be found in children with physiologic phimosis, even with ballooning of the foreskin.

Given that most cases of phimosis are probably physiologic and will resolve spontaneously over time,

the question remains which children to treat either medically or surgically. Little agreement exists in the literature. Some urologists would question whether true phimosis can exist before age 5 years and, therefore, whether any treatment need be initiated. Others use the age of 3 years as an upper limit and would at least initiate a trial of steroid creams (if no indication for surgery) at that time. Some urologists argue in favor of treating children who are younger (older than 3 years but younger than 5 or 6 years). Their research shows superior adherence with treatment at a younger age because the parents are still able to apply the cream. When older children become responsible for cream application, adherence, and, therefore, success of therapy, decreases. However, other studies have not necessarily shown any preferential success in younger children.

## PARAPHIMOSIS

### Definition

Paraphimosis, unlike phimosis, is a urologic emergency. It occurs when the foreskin is retracted and is not replaced immediately and becomes trapped behind the corona. Paraphimosis may happen during cleaning or during a procedure such as catheterization. The fibrous ring at the base of the corona causes venous congestion, leading to extreme penile pain and swelling of the glans with a collar of swollen foreskin at the coronal sulcus. If no treatment is initiated, then ischemia and necrosis of the glans can result.

### Management

The goal of treatment is to replace the foreskin in its normal position. If the condition is in its early stages, the foreskin may then be replaceable manually without sedation. As the condition progresses, anesthesia in the form of penile block, sedation, or general anesthesia may be required. Gentle persistent pressure is the goal of treatment to decrease edema and allow reduction of the foreskin. In infants and children, allowing an application of 2.5% topical lidocaine to take effect may allow manual reduction to be more successful. Sometimes an incision must be made in the fibrous ring or multiple punctures must be made in the glans to relieve swelling, but such interventions should only be undertaken by a urologist.

## BALANOPOSTHITIS

### Definition

Balanoposthitis is characterized by erythema and edema of the foreskin that produces purulent discharge from the preputial orifice. Occasionally, edema can involve some of the penile shaft as well, and patients may complain of dysuria. The condition usually occurs when the foreskin is wholly or partially retractable. In children, balanitis occurs most often between the ages of 2 and 5 years and is more commonly nonspecific balanitis, caused by poor hygiene, trauma, or irritation from soaps or detergents.

### Management

The treatment for nonspecific balanoposthitis includes local hygienic measures such as sitz baths, gentle

cleaning, and 1% hydrocortisone cream. If irritation does not resolve, then treatment with antimicrobials may be necessary, with the most common causative organisms being *Staphylococcus*, coliforms, *Pseudomonas*, and *Candida*. Another potential cause is *Streptococcus*, which can cause a thin purulent discharge in the preputial-glanular sulcus (but not from the urethra) associated with a red, glistening glans. If there is generalized redness with swelling progressing up the penile shaft or accompanying streaks, there should be a low threshold for hospital admission and IV antibiotics. If taking oral antibiotics, patients should be followed closely to monitor progress and ensure compliance. Sexually transmitted infections (gonorrhea and chlamydia) must also be considered when purulent discharge from the urethra is present, and therefore appropriate diagnostic tests (eg, DNA probes) should be obtained. The presence of sexually transmitted infections in the absence of purulent discharge is extremely unlikely in a prepubertal boy.

Surgical treatment, that is, circumcision, is usually considered only for recurrent episodes of balanoposthitis.

### WHEN TO REFER

Phimosis:

- Obvious or suspected penile deformities
- Failure of topical steroids
- Balanitis xerotica obliterans (BXO)
- Parents desire circumcision
- Association with urinary tract abnormalities/obstructive uropathy

Paraphimosis: failure of manual reduction

Balanoposthitis: recurrent episodes

### WHEN TO ADMIT

Paraphimosis: Failure of manual reduction with vascular compromise of the glans

Balanoposthitis:

- Swelling of the penis with redness and streaking
- Systemic infection or sepsis
- Inability to urinate
- Vascular compromise of the glans

### Chapter 313

## PIERRE ROBIN SEQUENCE

Elizabeth A. Sellars, MD; Robert J. Hopkin, MD

### DEFINITIONS

Pierre Robin syndrome, increasingly known as the Robin sequence or Pierre Robin sequence, comprises the triad of micrognathia, glossoptosis, and obstructive apnea. It is a highly heterogeneous condition. Physicians have used varying sets of criteria to make this diagnosis, which has resulted in widespread confusion. The most appropriate definition is the original description by Pierre Robin, a French stomatologist. In 1923, he described a condition consisting of micrognathia, glossoptosis, and airway compromise. Cleft palate is often associated and has been substituted for respiratory distress. Nevertheless, the initial description from 1923 is the best definition. It is important to have one common definition for families and physicians to communicate to each other appropriately and for future studies of this condition because treatment often involves a multidisciplinary approach that depends on consistent terminology.

Micrognathia is shortening and narrowing of the mandible and chin (Figure 313-1, Figure 313-2, Figure 313-3, and Figure 313-4). Micrognathia often coexists with retrognathia, which is posterior positioning of the lower jaw. These are two distinct entities. Glossoptosis is posterior displacement of the tongue into the pharynx. This may cause airway obstruction, which often affects both breathing and feeding. A cleft palate is often associated with micrognathia and glossoptosis. It can be U-shaped or V-shaped and can involve the soft palate, hard palate, or both.

A point of confusion with Robin sequence is that it is known by many names, including Robin sequence, syndrome, anomalad, and complex. A sequence is a chain of events in which a mechanical disruption or initiating anomaly causes another anomaly or pattern of anomalies. A syndrome is simply a group of abnormalities (often seemingly unrelated) with an initial cause that produces a recognizable pattern.

### ETIOLOGY

In children with Robin sequence, the primary pathology is micrognathia. The initial disruption is interference with normal growth and development of the mandible, which begins to form at 7 weeks' gestation. This leads to posterior displacement of the tongue and interference with the palatal shelves, which close at 11 weeks' gestation. Because of the abnormal mandible,

**Figure 313-1** A newborn with micrognathia and intact palate. Note clinical micrognathia. This patient experienced mild to moderate glossoptosis with airway obstruction that resolved without surgical intervention.

**Figure 313-2** Side view of an infant with micrognathia and glossoptosis but no cleft palate. Note that the degree of micrognathia seen on physical examination often is not predictive of the degree of respiratory or feeding problems.

the tongue stays high and retroposed and impinges against the airway, causing breathing and feeding compromise.

Robin sequence can be an isolated finding or part of another syndrome. Depending on the definition, about 50% of Robin sequence cases are associated with a genetic syndrome or other anomalies. Stickler syndrome is the most common identifiable syndrome associated with Robin sequence and is associated with dysplasia of the orofacial skeletal system. There are at least 50 recognizable syndromes known to be associated with Robin sequence. These include some relatively common conditions, for example, deletion 22q11.2 (velocardiofacial) syndrome and fetal alcohol syndrome (Table 313-1).

**Figure 313-3** Face on view of an infant with micrognathia

**Figure 313-4** Alternate view of newborn with micrognathia.

Table 313-1 Conditions Associated With Robin Sequence	
NAME	DESCRIPTION
Beckwith-Wiedemann syndrome	Macroglossia, risk for tumors, omphalocele, hypotonia, hypoglycemia, overgrowth, hemihypertrophy, visceromegaly
Campomelic dysplasia	Small stature, hypertelorism, congenital limb bowing, clubfoot, intellectual disability, sex reversal
Catel-Manzke syndrome	Abnormal index fingers, hand malformations
CHARGE association	Coloboma of the eye, heart malformation, choanal/esophageal atresia, intellectual disability, short stature, sensorineural hearing loss, abnormal ears
Fetal alcohol syndrome	Low birth weight, growth restriction, congenital heart defect, short palpebral fissures, long smooth philtrum, abnormal cognition, behavioral issues
Fetal hydatoin syndrome	Growth restriction, abnormal cognition, hypoplastic nails
Freeman-Sheldon syndrome	Joint contractures, whistling-shaped mouth, small stature
Microdeletion and duplication syndromes	Dysmorphic features, poor growth, intellectual disability, limb/digit abnormalities.
Moebius sequence	Palsy of sixth and seventh cranial nerves, limb defects
Smith-Lemli-Opitz syndrome	Cholesterol deficiency, intellectual disability, hypotonia, genital hypoplasia, kidney abnormalities, heart abnormalities, polydactyly, contractures
Stickler syndrome	Myopia, detached retina, joint laxity, flat face, marfanoid body
Treacher Collins syndrome	Conductive hearing loss, microtia, facial skeletal defects, colobomas
Velocardiofacial syndrome	Heart defects, developmental delay, hypotonia, hypocalcemia, nasal voice, tapering fingers

EPIDEMIOLOGY

The incidence of Robin sequence is about 1 in 2,000 to 30,000. The true number is not known because of the differing criteria used among physicians and in studies.

DIAGNOSTIC APPROACH

Robin sequence is a clinical diagnosis. There are no universally accepted tests or imaging studies to diagnose micrognathia or retrognathia. However, if a genetic syndrome is suspected related to the micrognathia, testing for the genetic condition may be available. Often, suspicion arises when an infant feeds poorly or cannot maintain his or her oxygen saturation, and closer examination reveals micrognathia. If Robin sequence is suspected, prompt clinical evaluation is

crucial because obstructive apnea can lead to long-term complications. Comprehensive evaluation should be done by any available pediatric otolaryngologist, pulmonologist, speech therapist, anesthesiologist, craniofacial surgeon, and geneticist. Many larger hospitals have a craniofacial team readily available.

The initial evaluation should include a family history focusing on individuals with Robin sequence or cleft palate. This may suggest a genetic cause. For example, family members with high myopia or a detached retina suggest Stickler syndrome. In addition, a prenatal history of maternal teratogen exposure, such as diabetic embryopathy or alcohol consumption while pregnant, is important. A history of oligohydramnios is relevant as constraint on the mandible during fetal development is thought to prevent its normal growth.

Similarly, anything that decreases fetal movement can decrease mandibular growth; therefore, most causes of severe hypotonia that are prenatal in onset can be associated with Robin sequence.

Even if no recognizable syndrome is identified in the infant with Robin sequence, genetic evaluation should be strongly considered. There are hundreds of genetic syndromes associated with micrognathia. It has been reported that about 35% of Robin sequence cases are syndromic. Thus, any child with Robin sequence ideally should be evaluated by a clinical geneticist. Historically, chromosome analysis was the initial screening tool for genetic abnormalities. Recently, advances in genetic testing have discovered chromosomal microdeletions and microduplications linked to multiple congenital anomaly syndromes. These chromosomal abnormalities are identified with a DNA microarray, which has much better sensitivity than chromosome analysis. Deletion 22q11.2 is a common cause of Robin sequence, and fluorescence in situ hybridization (FISH) analysis can identify this syndrome. This technique is not a screening tool because it tests only for the specific disease in question. After the initial examination, a number of genetic tests should be considered with special attention to neurologic findings or malformations unrelated to the micrognathia. If growth and feeding abnormalities persist after airway obstruction has been addressed, genetic testing should also be considered.

Prenatal diagnosis is not always possible, but advances in prenatal imaging and the availability of high-resolution and three-dimensional ultrasound make severe cases of micrognathia identifiable in the fetus. This is useful because these infants may require intubation in the delivery room. Prenatal management should include delivery in a hospital with a neonatal intensive care unit and evaluation by a neonatologist with immediate access to an airway specialist. For extreme cases, it may be desirable to have an otolaryngologist immediately available.

## EVALUATION

An infant identified prenatally with severe micrognathia may need immediate intubation after delivery. Other infants may simply require monitoring for episodes of apnea, decreased oxygenation, and poor feeding. If an infant has no episodes of desaturation and gains weight, no intervention is necessary. However, if an infant has apnea episodes, has oxygen desaturations, cannot feed without desaturation, or fails to gain weight, further evaluation and management is needed.

Obstructive apnea is the most critical problem for an infant with Robin sequence. This may not be an immediate problem but can sometimes become evident later in infancy. At the mildest end of the spectrum, there may be little or no evidence of respiratory difficulty. However, there may be increased caloric expenditure and early fatigue with feeding owing to decreased respiratory reserves. This may result in inadequate weight gain. This relatively mild or subtle presentation is most readily confirmed with a polysomnogram that will demonstrate frequent obstructive events with or without oxygen desaturation.

If apnea spells are suspected, the airway should be examined closely, likely with nasoendoscopy by an

otolaryngologist and bronchoscopy by a pulmonologist. It is important to analyze the position of the tongue and evaluate for any lower airway disease. Unlike laryngomalacia, micrognathia may lead to obstruction with both inspiration and expiration on an endoscopic exam. A polysomnogram or sleep study evaluates apnea spells during sleep in various positions. A barium swallow study with speech evaluation is a better study to evaluate feeding and respiratory dynamics while awake and during feeding. Finally, three-dimensional computed tomography (CT) maps out the bony anatomy, should surgical interventions be needed. This type of CT scan allows the mandible to be viewed from almost any angle. It is important to take any airway compromise seriously because long-term consequences include hypoxia, failure to thrive, dehydration, electrolyte imbalance, cor pulmonale, and death.

Infants with Robin sequence may also have problems with both breastfeeding and bottle feeding, usually secondary to airway obstruction. The suck-swallow-breathe coordination can be very difficult in infants with micrognathia and glossoptosis. Feeding seems to exacerbate limited respiratory reserve. Often, the infant cannot compress the nipple sufficiently. If a cleft palate is also present, feeding is further compromised because suction cannot be generated for feeding. These infants are at increased risk for aspiration of formula or breast milk. Feeding may take so much work that the infant expends more energy than he or she gains, affecting weight gain. If the Robin sequence is part of an associated syndrome, feeding problems and weight gain may be further compromised.

## TREATMENT APPROACH

### Nonsurgical

Treatment algorithms include nonsurgical and surgical interventions. About half of infants with Robin sequence could be managed with nonsurgical interventions. The initial approach to any infant suspected of Robin sequence is to place that infant in a prone position. Gravity will pull the tongue forward, often relieving the glossoptosis and creating an open airway. A polysomnogram should be obtained because pulse oximetry alone is not sensitive enough to detect frequent but brief apneas. If the polysomnogram is normal or mildly abnormal with few apnea spells, positioning and supplemental oxygen through nasal cannula may be the only intervention required. If the polysomnogram demonstrates moderate to severe abnormalities, a nasopharyngeal airway can be placed while further treatments are considered. There are several nonsurgical feeding interventions. Positioning the infant on his or her side or semireclined during feeding can alleviate respiratory distress. If this does not resolve the issue, a skilled speech therapist or occupational therapist should evaluate the infant to optimize feeding technique. Breastfeeding usually requires consultation with a lactation specialist familiar with these issues and almost always results in use of pumping and bottle feeding. Close monitoring of weight gain and apnea spells is essential. Some mothers are able to breastfeed after distraction if they are still lactating and there is no cleft. When a cleft palate is present, a special

bottle should be used with compressibility allowing the milk to be squeezed into the infant's mouth. These bottles include the Haberman Feeder, Pigeon Cleft Palate Nurser, and Mead Johnson Cleft Palate Nurser. Often, an NG tube must be placed for adequate caloric intake, especially during mandibular distraction. Oral feeding often improves significantly after mandibular distraction. In some cases, a G-tube must be considered if intake does not improve after mandibular distraction. A G-tube is also required for infants with severe neurologic deficits and high risk for aspiration.

### Surgical

Surgical interventions for apnea spells depend on the severity and take into account the entire clinical picture. Tracheostomy historically was the primary option for severe, persistent obstruction. It is still performed for many reasons, including airway obstruction, chronic cardiopulmonary disease, and neurologic compromise. Over time, it has been shown that only a small subgroup of infants with respiratory distress due to Robin sequence require intubation or tracheostomy. If the infant has evidence of neurologic impairment, a tracheostomy may be needed to prevent aspiration and other complications. If there is an underlying genetic syndrome with many organ systems involved, such as cardiac and pulmonary, a tracheostomy may be necessary. Finally, a tracheostomy may be necessary if other airway management options have failed.

During the past several years, mandibular distraction osteogenesis has gained favor in many craniofacial centers. Originally, mandibular distraction osteogenesis was done for successful decannulation in older children with tracheostomies using rib bone as grafts. Now, however, this technique is done as a primary treatment to avoid tracheostomy with its associated complications, increased mortality rate, and delayed speech development. Distraction devices can be used on multiple planes of a bone and can be placed internally or externally. Of note, current options are usually not associated with severe scarring.

For Robin sequence, this technique slowly elongates the mandible by bilateral corticotomies (partial fractures) with placement of percutaneous wires and distraction devices. Mandibular distraction relies on the body's ability to lay down new bone when the ends of a bone are separated. After a latency period of 24 to 48 hours, the distractor is turned daily to achieve about 1 to 4 mm of distraction per day. The goal is to bring the base of the tongue forward, relieving the glossop-tosis and apnea. Infants who are otherwise stable can sometimes be taken home after parents are taught to manipulate the distractor device. On average, there are 2 to 4 weeks of active distraction and another 4 to 6 weeks for bone consolidation. During the period of distraction, infants are often fed through a nasogastric (NG) tube. Some facilities allow oral feeding during distraction, but this is not the standard at most places. Importantly, distraction elongates muscle, blood vessels, nerves, and mucosa as well as bone. New techniques for distraction osteogenesis include miniaturized and absorbable distractor plates. Although a large number of children are distracted at a young age (infancy to

3 years old) for reasons illustrated earlier, many patients are distracted at 6 to 7 years old if airway issues permit.

An older technique is tongue-lip adhesion, which sutures the tongue base to the anterior mandible. This method has been abandoned by most surgeons because of the side effects of aspiration, feeding abnormalities, speech delay, and subsequent tongue atrophy and weakness. Less than 15% of pediatric centers report use of this technique.

## SURGICAL COMPLICATIONS

Complications of mandibular distraction osteogenesis are numerous but rare and comparable to the alternative of tracheostomy. These complications can include bone malunion or malalignment requiring repeat distraction. There is potential disturbance of mandibular growth at the temporomandibular joint. The facial nerve can be injured. Tooth loss or damage to underlying tooth buds can occur. More commonly, the skin where the distractor inserts can become infected if not properly cleaned. Tracheostomies carry the risks for dislodgement or occlusion of the tube, buildup of granulation tissue, delayed speech, and recurrent infections—all related to a chronic foreign body in the airway.

## PROGNOSIS

Robin sequence has a broad range of phenotypes associated. With prompt identification of isolated Robin sequence in a neonate who demonstrates respiratory distress, there should be no impact on life span. The immediate management is straightforward, and the initial tools for treating most children (positioning, oxygen, and monitors) are readily available in any hospital with newborn care. Most patients do not require surgical management as neonates. Infants with isolated Robin sequence and those with Stickler syndrome (comprising >50% of cases) should have normal cognition, good growth, and a normal life span. Infants and children with syndromic Robin sequence are at increased risk for long-term morbidity and mortality because of the risks inherent to the specific syndrome. There should be a low threshold for involving a geneticist with any case of Robin sequence to identify these high-risk infants. Furthermore, a team approach should be applied in general for these infants because a single solution cannot be broadly applied, but careful assessment can contribute to appropriate risk stratification and management.

### WHEN TO ADMIT

- Infants with poor weight gain in the first week of life
- Stridor or other respiratory symptoms on examination (or by history)
- Suspicion of other malformations or neurologic abnormalities, requiring further evaluation by specialists

### WHEN TO REFER

- Craniofacial management is expected.
- A surgical intervention or assessment is likely (ie, for airway or feeding).
- Poor feeding or respiratory distress in neonates

## Chapter 314

# PINWORM INFESTATIONS

Craig M. Wilson, MD

## ETIOLOGY

Pinworm (*Enterobius vermicularis*) infestation is exceptionally common. When sought carefully, the parasite can be found in at least 30% of children worldwide, and infestation rates may approach 100% in child care centers, boarding schools, and institutions. Good sanitation and advanced socioeconomic status are feeble deterrents to pinworms. Adults are often infested, and finding pinworms in all members of a family is not uncommon. The discovery of *Enterobius* eggs in 10,000-year-old human coprolites from the Hogup and Danger caves in Utah proves that the parasite was no stranger to our ancestors.

*E. vermicularis* is a white, threadlike worm that lives primarily in the cecum and adjacent bowel. The gravid female worm, which is approximately 1 cm long, migrates to the perianal area to deposit up to 10,000 eggs and dies shortly thereafter. Thus, the infestation would be self-limited were it not for reinfestation. Unfortunately, the eggs, which are approximately 50 × 30 μm, oval, flat on 1 side, and thin shelled, become infective in approximately 6 hours. Moreover, *Enterobius* eggs are rather hardy and may survive for weeks in dirt, house dust, clothing, and bed sheets. Survival is enhanced by lower temperature and if inhaled and swallowed. Pets may carry eggs in their fur.

Autoinfestation occurs readily through ingestion of eggs if the host scratches the perianal area or does not wash the hands thoroughly after defecating. Once ingested, the eggs hatch in the upper small intestine, and the worms mature while migrating to the lower ileum and ascending colon. The cycle from ingestion to deposition of eggs is approximately 4 to 6 weeks,

although the adult worms may live up to 13 weeks. The worm burden within an individual may reach the hundreds; but within an infested population, most individuals would be harboring few parasites.

## CLINICAL MANIFESTATIONS

Localized perianal pruritus is the most commonly reported symptom, but one third or more of infestations are asymptomatic. Restlessness and fitful sleep are common complaints, as are secondary excoriation and dermatitis. Migrating pinworms entering the vagina or urinary tract in female patients may lead to genitourinary symptoms. The general lack of abdominal complaints supports the notion of minimal gastrointestinal abnormality with this parasite.

In rare cases, pinworms invade tissue and cause a granulomatous reaction, and granuloma-containing worms have been an incidental finding in the gut, vulva, cervix, fallopian tubes, peritoneum, and bladder. Inflammation associated with the parasite has been found in cases of appendicitis and eosinophilic colitis, suggesting causality with *E. vermicularis*.

## LABORATORY EVALUATION

Diagnosis is dependent on identifying either the adult worms or the eggs. Occasionally, adult pinworms may be noted near the anus, particularly in the morning. Eggs are seldom found in the patient's feces even if concentration techniques are used. The best way to make a diagnosis is to use the cellophane tape technique. When the child awakens in the morning, the adhesive side of a 2-inch strip of clear cellophane tape should be pressed against the perianal skin; this task is most easily done using a tongue depressor (commercially produced kits are available for this purpose). The tape should then be placed on a microscope slide with the adhesive side down and scanned for eggs. The eggs are naturally transparent, and staining with lactophenol cotton blue enhances detection. A single test should detect at least 50% of infestations, 3 tests will detect 90%, and 5 tests will detect virtually 100%.

## PREVENTION AND THERAPY

Elimination of pinworm from patients is extremely difficult. The ubiquity and infectivity of the parasite, the high level of infestation in symptomatic patients, and its persistence in the environment all contribute to the difficulty of eradication. Moreover, vigorous pursuit of a permanent cure may provoke needless turmoil and anxiety in the family. When the diagnosis is confirmed in a patient who has symptoms, the following approach is reasonable.

Both initial treatment of only a confirmed individual patient or therapy for the entire family are reasonable approaches. A single dose of either mebendazole (100 mg for all ages) or albendazole (400 mg for all ages) is extremely effective and has virtually no side effects. Pyrantel pamoate, administered as a single dose of 11 mg/kg (maximum, 1 g), is also effective; a transient headache and abdominal complaints have been reported with this therapy. All of these treatments are effective against the adult worms only, and therefore therapy is usually repeated in 2 weeks to eradicate any emerging parasites.

Other simple, prudent measures can be followed, such as clipping the fingernails (a favorite repository for eggs), washing the hands frequently, and showering daily in the morning. Wearing tight-fitting cotton underpants and applying a bland ointment (eg, petroleum jelly) to the perianal region may limit dispersal of the eggs. The floors in sleeping areas should be cleaned thoroughly, particularly in cases of recurrence. Clothing and bedding should be washed at the time of treatment. The most important aspects of treatment, however, are humility on the part of the physician and reassurance of the family.

### TOOLS FOR PRACTICE

#### Engaging Patient and Family

## Chapter 315 PNEUMONIA†

Michael Light, MD

### INTRODUCTION

Community-acquired pneumonia (CAP) is a common problem worldwide and causes considerable mortality. In North America, the annual incidence is reported to be 34 to 40 cases per 1,000 in children younger than 5 years. The incidence among adolescents is about 7 per 1,000 between 12 and 15 years old. In developing countries, pneumonia is even more common. The mortality rates are high, with 4 million deaths per year, which means pneumonia is the number 1 cause of death in children younger than 5 years in developing countries.

Community-acquired pneumonia is defined as pneumonia that is acquired outside the hospital environment, whereas nosocomial pneumonia is acquired in the hospital environment. The diagnosis of pneumonia is usually made on the basis of signs and symptoms and supported by a radiologic diagnosis. The World Health Organization (WHO) defines pneumonia on the basis of the clinical findings because chest radiology is not readily accessible in many parts of the world.

The agents that cause pneumonia are varied and include bacteria, viruses, fungi, and protozoal organisms. It can also be caused by aspiration and exposure to toxic substances, such as chlorine.

### PATHOLOGY

The pathology of pneumonia is described as either

- Lobar
- Bronchopneumonia
- Interstitial
- Miliary

Lobar pneumonia has 4 stages. The initial stage is congestion, where the alveoli are filled with fibrinous fluid, neutrophils, and bacteria. This stage occurs within 24 hours of infection. The second stage usually occurs on days 2 to 3 and is called red hepatization. The lung reddens and is of the consistency of liver. The alveoli are filled with fibrinous inflammatory exudates with increased numbers of neutrophils and red cells that contribute to the color. The consolidated lobe is airless and evident on chest radiography. The pleura is usually thickened, and a pleural rub may be heard. The next stage is called grey hepatization, where the alveoli are filled with fibrin threads and neutrophils and the red cells are much fewer in number. The lung is still stiff, and the alveolar walls are thickened and fibrosed. The fourth stage is resolution as the inflammatory exudates are resorbed.

Bronchopneumonia is more patchy and, as the name suggests, there is suppurative inflammation of the bronchi and surrounding alveoli. The exudates fill bronchi and bronchioles and affect the adjacent alveoli while the distant alveoli may be free of exudates. The patchy consolidation may affect one or several lobes and is usually bilateral. The lobes more involved include the dependent lung zones and the bases.

Interstitial pneumonia results from inflammation that is within the alveolar wall rather than the alveolar air space. The infiltrate tends to consist of lymphocytes and macrophages, and hyaline membranes may line the alveolar spaces.

An additional category is miliary, which occurs with hematogenous spread to the lung, which leads to multiple discrete lesions often throughout both lungs.

Bacterial pneumonia often follows a viral upper respiratory infection (URI). Lobar pneumonia is most commonly bacterial, including atypical bacteria. Bronchopneumonia may be caused by bacteria, atypical bacteria, or viruses. Interstitial pneumonia may result from measles and *Bordetella pertussis*, as well as non-infectious causes including aspiration. Miliary pulmonary infection is most commonly seen in tuberculosis, histoplasmosis, and coccidioidomycosis. Immunocompromised children are at risk for miliary herpesvirus, cytomegalovirus, or varicella-zoster virus.

### ETIOLOGY

It is difficult to study the etiology of pneumonia because the causes are so diverse, and what is found in one community may not apply to another community. A study of 154 hospitalized children with CAP looking carefully for an infectious cause showed that it was caused by identifiable bacteria in approximately 60% of cases, of which 73% were caused by *Streptococcus*

†This chapter has been adapted and updated from the AAP policy manual *Pediatric Pulmonology*.

*pneumoniae*. A viral cause was found in 45% of cases, of which 23% had concurrent bacterial and viral disease. They also found *Mycoplasma* spp. in 14% and *Chlamydomphila* (*Chlamydia*) *pneumoniae* in 9%.

## CLINICAL FEATURES

The symptoms and signs of pneumonia vary from subtle to highly suspicious. Table 315-1 shows age-related symptoms and signs that suggest the diagnosis of pneumonia. In a pediatric emergency department study in the United States, the finding of respiratory rate alone and clinical impression of tachypnea did not discriminate between those who had radiographic evidence of pneumonia and those who did not, whereas the children who exceeded the WHO respiratory rate thresholds were more likely to have pneumonia. The

most common presentation is cough and fever, which is very nonspecific. The appearance of the child is important; signs of respiratory distress, including retractions and nasal flaring, and abnormal auscultation, will aid the physician in arriving at the diagnosis of pneumonia.

## DIAGNOSIS

The microbiologic diagnosis of pneumonia is difficult to prove in many cases without extensive investigation. The age of the child will suggest the most likely cause, and it is also helpful to be aware of which organisms are in the community at the time. Pneumonia in the pediatric population is most common in infants and toddlers and least common in adolescents.

Box 315-1 lists the more likely causes of pneumonia based on age.

**Table 315-1** Symptoms and Signs of Pneumonia

	≤2 MONTHS	2–12 MONTHS	1–5 YEARS	>5 YEARS
<b>Respiratory rate</b>	≥60/min	≥50/min	≥40/min	≥30/min
<b>WHO threshold</b>

WHO, World Health Organization.

### BOX 315-1 Age-Related Etiology of Pneumonia in the Immunocompetent Child

#### 2 MONTHS AND YOUNGER

- Group B streptococcus (*Streptococcus agalacticae*)
- Pneumococcus (*Streptococcus pneumoniae*)
- *Staphylococcus aureus* (MSSA, MRSA)
- *Listeria monocytogenes*

#### 2–12 MONTHS

- Pneumococcus
- RSV
- Parainfluenza virus
- Influenza virus
- Adenovirus
- Human metapneumovirus
- *Chlamydia trachomatis*
- Pertussis

#### 1–4 YEARS

- Pneumococcus
- Parainfluenza

- Influenza
- Adenovirus
- RSV
- hMPV
- *Mycoplasma pneumoniae*

#### 5–12 YEARS

- *Mycoplasma*
- *Pneumococcus*
- Group A Streptococcus (*Streptococcus pyogenes*)
- Viruses

#### 12 YEARS AND OLDER

- *Mycoplasma*
- *Chlamydomphila pneumoniae*
- *Pneumococcus*
- Group A Streptococcus
- Viruses

hMPV, human metapneumovirus; MRSA, methicillin-resistant *Staphylococcus aureus*; MSSA, methicillin-sensitive *Staphylococcus aureus*; RSV, respiratory syncytial virus.

### Infants to School Age (1 to 4 Years of Age)

After 1 month of age, cough is the most common presentation of pneumonia. A viral upper respiratory illness commonly precedes the pneumonia. If the pneumonia is bacterial a significant fever is usually present, whereas in viral or atypical infections the fever may be low-grade. Generally, though, the height of the fever is a poor indicator of etiology. Most cases of pneumonia are viral, and respiratory syncytial virus (RSV) is the most common pathogen. Although RSV principally causes bronchiolitis, it is also a common cause of pneumonia. In children older than 2 years, RSV does not cause lower respiratory tract infection except in immunocompromised (especially transplant) patients. Respiratory syncytial virus causes significant morbidity and mortality in the elderly. Parainfluenza type 3 occurs year-round, with peaks in the spring, and types 1 and 2 are typically seen in the fall.

### 5 Years of Age to Adolescence

The most common cause of bacterial pneumonia is *S pneumoniae*, but *Mycoplasma* is increasingly being diagnosed as the cause of CAP. Group A *Streptococcus* is also increasingly being diagnosed. Various viruses cause pneumonia, including adenovirus, influenza, parainfluenza, and RSV (in the immunocompromised and transplant patient).

### Laboratory Findings

As previously noted, the diagnosis of pneumonia is clinical and is supported by the radiographic changes if a radiograph is performed. Laboratory investigation is usually of limited value in the outpatient evaluation of a child with pneumonia.

Complete blood cell count may reveal an elevated white count greater than 20,000 cells/ $\mu$ L with pneumococcal pneumonia. Atypical lymphocytes may be found with viral infections, but the finding is nonspecific. It is not considered essential to attempt to find the etiologic agent routinely in children who were previously well. Pneumonia in children does not usually have bacteremia, and blood culture is not routinely required in immunocompetent children unless they are hospitalized.

If the child is critically ill or immunocompromised, blood culture is more likely to be positive. Sputum Gram stain with culture and sensitivity may be considered in the older child. If the child does not respond to initial therapy within 72 hours or if there is a rapid progression of symptoms, further testing may be indicated.

Elevation of C-reactive protein may predict more severe disease, but it does not differentiate bacterial from viral pneumonia.

If the child has a pleural effusion and has not received antibiotics, a pleural tap should be considered. If antibiotics have been given, the yield from pleural tap is low. Polymerase chain reaction (PCR), if available, may be helpful with further etiologic diagnosis.

### Imaging

The standard imaging for diagnosis of pneumonia is a 2-view plain chest radiograph. It is not possible to differentiate between viral and bacterial disease. Lobar

pneumonia, with disease restricted to the involved lobe, is more suspicious for bacterial pneumonia. Perihilar scattered infiltrates, hyperinflation, and hilar adenopathy are more likely in viral pneumonia than in bacterial pneumonia. Round pneumonia, seen in younger children, is likely of bacterial etiology, particularly *S pneumoniae*, but also includes *Staphylococcus aureus* and *Klebsiella* species. Ultrasound is increasingly being used to evaluate pulmonary problems and can assist in evaluation of lobar consolidation and pleural effusion. A computed tomography (CT) scan or ultrasound is indicated if there are complications.

## BACTERIAL CAUSES OF PNEUMONIA

Bacterial pneumonia is an important cause of death if untreated, especially in developing countries. Although most children with bacterial pneumonia improve without sequelae, children with pre-existing conditions may be at increased risk for morbidity, including subsequent infections because of scarring in the lungs. The immune status of the child also affects the risk of mortality and morbidity. Tuberculosis remains an important cause of pneumonia.

### Gram-Positive Organisms

#### *Pneumococcus*

*Streptococcus pneumoniae* was the most common bacterial cause of lower respiratory infection before the institution of the pneumococcal conjugate vaccine, PCV-7, in 2000. Since then, invasive pneumococcal disease was reduced by 80% for children younger than 2 years. This finding may increase because a 13-valent pneumococcal conjugate vaccine (PCV-13) replaced PCV-7 in the routine childhood immunization schedule in 2010. PCV-13 is recommended by the US Food and Drug Administration for use in preventing pneumococcal disease in all infants and young children beginning as young as 6 weeks of age. Surveillance is also indicated for nonvaccine serotypes. Although invasive pneumococcal disease has decreased, complicated pneumonia has increased significantly across the United States, and these cases tend to be from nonvaccine serotypes. Use of PCV-13 coupled with pneumococcal polysaccharide vaccine (PPSV-23) is now recommended by the AAP for children and adults with certain chronic medical conditions or cochlear implants to provide greater protection.

Pneumococci are gram-positive diplococci, which are colonized in the upper respiratory tract of many people. Transmission is by droplet, and the incubation period is short (sometimes 1–3 days). Populations at higher risk for invasive pneumococcal disease (pneumonia, meningitis, and sepsis) are shown in Box 315-2.

Pneumococcal pneumonia may be preceded by a mild URI. Infants may present with a sudden rise in body temperature, possibly a seizure, and diarrhea and vomiting. Cough may be absent, but evidence of respiratory distress includes tachypnea, nasal flaring, and perioral cyanosis. The older child usually presents with fever, chills, dyspnea, and pleuritic chest pain. Older children may have sputum production, and streaks of blood may be apparent in the sputum.

Examination of the chest may not be abnormal in the infant and young child. The older child will usually

### BOX 315-2 Children at Increased Risk for Invasive Pneumococcal Disease

- Children <36 months
- Children with sickle cell disease
- Children with asplenia
- Children with human immunodeficiency virus infection
- Children with cochlear implants
- Children with chronic disease including asthma, immune deficiency (including transplants), cardiac disease, pulmonary disease, renal insufficiency, and diabetes mellitus are at presumed high risk, but the data are insufficient to calculate rates

demonstrate crackles and dullness to percussion with bronchial breathing over the involved lobe. Friction rub is not often elicited. Abdominal pain in the older child is a common symptom, especially if the infiltrate(s) involve the lower lobe of either lung.

Laboratory findings also are not consistent. Although not indicated in the outpatient setting, a white blood cell count over 20,000/ $\mu$ L with the clinical picture of pneumonia is certainly suspicious of pneumococcal disease. The yield from blood culture is low, but the sputum findings of many polymorphonuclear leukocytes with gram-positive diplococci is almost diagnostic. Young age is a barrier to sputum collection. Antigen detection is not considered useful for diagnosis except for pleural fluid.

The chest radiograph in children with pneumococcal pneumonia may initially demonstrate a lobar pattern and then extend beyond the lobar boundaries. It is the most common cause of “round pneumonia” pattern. On occasion, the markings may be patchy or interstitial. The chest radiograph is not consistently able to confirm the diagnosis of a bacterial or viral pneumonia because of the overlap between findings.

**MANAGEMENT.** The clinical course of pneumococcal pneumonia is usually rapid, with response to antibiotics causing reduction of fever within a few hours. In children with CAP proven or suspected to be of bacterial origin who are treated as outpatients, the AAP recommends amoxicillin or amoxicillin-clavulanate. In school-aged children (>5 years), the addition of a macrolide for coverage of atypical organisms is advised. In children ill enough to warrant hospitalization, the use of penicillin, ampicillin, or ceftriaxone and the addition of a macrolide is usually appropriate, and decisions for therapy should take into account local resistance patterns and immunization history. Complications may be systemic, with meningitis, carditis, peritonitis, and septic arthritis resulting from bacteremia. Pulmonary complications include pleural effusion and empyema. Inappropriate secretion of an antidiuretic hormone is common and may significantly reduce serum sodium.

#### Group A Streptococcus

Also known as *Streptococcus pyogenes*, group A  $\beta$ -hemolytic streptococcus is an uncommon cause of

pneumonia. It is important because the clinical course is aggressive and may result in necrotizing pneumonia. The clinical appearance of the child includes fever, chills, lethargy, cough, and dyspnea. The most common radiographic pattern is a patchy bronchopneumonia, but in a minority of cases there is lobar consolidation. Cavitation may occur, as well as pleural effusion with progression to fibrinopurulent empyema.

**MANAGEMENT.** The response to antibiotics tends to be slow, even with sensitive organisms. Complications are common and include pneumothorax, pneumatoceles, bronchiectasis, and bronchopleural fistula. Penicillin remains the treatment of choice, although ampicillin is an alternative.

#### Staphylococcal Pneumonia

*Staphylococcus aureus* was for a long time an uncommon cause of pneumonia in immunocompetent children, but it did occur in infancy. A virulent strain of community-associated methicillin-resistant *S aureus* (MRSA) has emerged and is now associated with life-threatening, complicated pneumonia. *S aureus* also occurs more commonly after influenza infection and other viral URIs. Staphylococci are gram-positive organisms that occur in clusters. Pneumonia results from inhalation of organisms or from bacteremic spread. The clinical picture varies from a mild respiratory infection with fever, cough, and tachypnea to a rapidly progressive illness with dyspnea, cyanosis, and septic shock. The initial radiographic appearance is multiple nodular infiltrates, usually unilateral, which in a few days become cavitory; subsequently, pneumatoceles form. Pneumothorax is common, especially in ventilated infants, and empyema is present in most cases.

The scenario described in the previous paragraph would likely be diagnosed as *S aureus* in an infant, but if the same findings were present in an older child other organisms would be more likely, including *Escherichia coli*, *Pseudomonas*, or *Klebsiella*. These children may be in an intensive care unit or immunocompromised. It is likely that the relative prevalence from *Pneumococcus* to *S aureus* is increasing in older children, and that there are increasing numbers of children with pneumonia caused by MRSA. Schultz and colleagues also compared complications between MRSA and methicillin-sensitive *S aureus* and found similar complication rates.

**MANAGEMENT.** If staphylococcal pneumonia is suspected, the increased prevalence of MRSA requires vancomycin or clindamycin for initial treatment until the sensitivities are known. Physicians should be aware of their local MRSA susceptibilities for these agents.

#### Gram-Negative Organisms

##### *Pseudomonas aeruginosa*

*Pseudomonas* is a gram-negative bacterium that has a predilection to moist environments. It is common to acquire *Pseudomonas*, with colonization in more than 50% of humans, and *Pseudomonas* often causes nosocomial infection. It is an unusual cause of pneumonia in healthy children. Pneumonia caused by *Pseudomonas* is a common complication of children with endotracheal tubes or tracheostomy. It is the dominant

organism in cystic fibrosis (CF). It occurs more often in children with poorly controlled human immunodeficiency virus (HIV) infection, neutropenia, and complement deficiency and those who are immunosuppressed. It is the most common cause of pneumonia in the intensive care environment. It has been reported following exposure in hot tub spas.

Although the typical color of sputum produced in pseudomonal pneumonia is green, this color may be seen with pneumococcal and *Haemophilus* infections. Untreated *Pseudomonas* pneumonia may progress rapidly to necrotizing bronchopneumonia. Pleural effusion is common, and the pneumonia may have a lobar or diffuse bilateral bronchopneumonia radiographic pattern.

**MANAGEMENT.** Treatment of *Pseudomonas* pneumonia should be with 2 antibiotics, usually an aminoglycoside and a  $\beta$ -lactam antibiotic. For children with chronic *Pseudomonas* infection, especially those with CF, there is a major problem with resistance to antibiotics.

### ***Burkholderia cepacia***

*Pseudomonas cepacia* was described initially by Walter Burkholder in 1949 and is now named *Burkholderia cepacia*. It is an important pathogen in CF causing pneumonia and has been reported to cause pneumonia in immunocompromised children, especially those with chronic granulomatous disease (CGD). *B cepacia* does not cause pneumonia in healthy children.

### ***Klebsiella pneumoniae***

*Klebsiella pneumoniae* is a gram-negative rod-shaped bacillus, and clinically the most important member of the *Klebsiella* genus of Enterobacteriaceae.

**CLINICAL FEATURES.** Pneumonia as a result of *K pneumoniae* is typically a nosocomial infection. It may also be community acquired, although it is rare in otherwise healthy children. Pneumonia tends to occur in immunocompromised or debilitated children. It is associated with an acute onset with fever and chills. The cough is productive and yields abundant thick sputum that is typically blood tinged and is known as red currant jelly sputum. *Klebsiella pneumoniae* pneumonia is usually complicated, and abscess formation, cavitation, and empyema are common. Infection is more commonly unilateral, occurring typically in the upper lobes.

**MANAGEMENT.** Hospitalization is indicated, including for CAP, because even with treatment there is significant mortality. Many *Klebsiella* organisms are resistant to multiple antibiotics so, rather than monotherapy, multiple antibiotics are indicated until antibiotic sensitivities are available. Potential choices are wide, including third-generation cephalosporins (eg, cefotaxime or ceftriaxone), carbapenems (eg, meropenem), amino-glycosides, and quinolones. Extended-spectrum  $\beta$ -lactamase- and carbapenemase-resistant strains may occur; thus, the pediatrician should consult with an infectious disease specialist.

### ***Legionella pneumophila***

Legionnaires' disease was first recognized in 1976 at an American Legion convention in Philadelphia. The organism that caused an outbreak of pneumonia was identified as a gram-negative bacillus, *Legionella*

*pneumophila*. While an unusual cause of pneumonia in children, it is important to recognize. It is more common in children who are immunosuppressed, and more than one-third of children in pediatric cases have been younger than 1 year. Transmission occurs by aerosolization and inhalation or aspiration of water containing the organism. It has been linked to contaminated water in hospitals and respiratory therapy equipment, as well as cooling towers; central air conditioning systems; evaporative coolers; hot water systems, including showers and hot tub spas; and ice-making machines. The disease is particularly prevalent in hotels, cruise ships, and hospitals that have outdated cooling systems. The incubation period is 2 to 10 days, and for milder disease, known as Pontiac fever, the incubation period is 1 to 2 days.

**CLINICAL FEATURES.** Legionnaires' disease presents with fever, chills, and cough, which is initially non-productive. Constitutional symptoms include headache, muscle ache, and sometimes ataxia (loss of coordination) and diarrhea or vomiting. The lung examination typically reveals crackles.

A blood test may reveal abnormal hepatic or renal function, and hyponatremia is common. Chest radiograph typically shows unilateral or bilateral bronchopneumonia.

**MANAGEMENT.** Clues to the diagnosis are the constitutional symptoms and the laboratory abnormalities including hyponatremia. Detection of *L pneumophila* serogroup 1 is aided by detecting *Legionella* antigen in the urine.

Azithromycin is the drug of choice for children with suspected or confirmed *Legionella* pneumonia. It is initially recommended by the AAP to give azithromycin intravenously, converting to orally when the child responds. Fluoroquinolones are bactericidal and can be used in adolescents and adults as well as immunocompromised children.

### **Anaerobic Organisms**

The most common anaerobic gram-negative bacilli (AGNB) to cause pneumonia are the pigmented *Prevotella* spp. The *Prevotella* spp. are important components of the bacterial flora of the mouth, nose, and nasopharynx. They are not often cultured because of the difficulty in specimen collection and growth in the microbiology laboratory.

Anaerobic organisms are common contributors to infections such as chronic sinusitis, chronic mastoiditis, chronic otitis media, and retropharyngeal abscess.

Pneumonia caused by anaerobic organisms results from aspiration of upper airway or gastric secretions. Severe gingival disease is a risk factor. Following aspiration there may be progression from pneumonia to necrotizing pneumonia, and AGNB is an important cause of lung abscess. Frequently, AGNB are recovered in culture along with Enterobacteriaceae, *Pseudomonas*, and *S aureus*.

The *Prevotella* are resistant to penicillin and typically susceptible to metronidazole and carbapenems.

### **Atypical Pneumonia**

The term *atypical pneumonia* is applied when the organism that causes the pneumonia does not fit the

category of bacteria or viruses. The agents that cause atypical pneumonia include *Mycoplasma pneumoniae*, *Chlamydia trachomatis*, *Chlamydophila pneumoniae*, and *Chlamydophila psittaci*.

### **Mycoplasma**

*Mycoplasma pneumoniae* is the most common cause of CAP in children older than 5 years, often called “walking pneumonia.” Disease from *M pneumoniae* may occur in children younger than 5 years.

The true incidence is unknown because many cases are treated empirically without confirmation of the diagnosis. There are no geographic limitations, and infection occurs year-round. There may be epidemics every 3 to 7 years, and outbreaks occur in schools and universities.

*Mycoplasma pneumoniae* is called mycoplasma because of the plasticity of the bacterial forms, which resemble fungal elements. Instead of a cell wall there is a cell membrane containing sterols, which are not present in most bacteria or viruses. Unlike viruses they do not require a cell to replicate and can grow in cell-free media, and like bacteria they contain both RNA and DNA.

### **Clinical Features**

*Mycoplasma pneumoniae* infections usually start with a URI with pharyngitis, cough, headache, and myalgias. There may be fever, which is usually lower than 102°F. The cough is initially nonproductive and can be severe and debilitating. Blood streaking of the sputum is not uncommon, and the coughing may cause chest pain that is nonpleuritic. In 5% to 10% of children the URI progresses to bronchitis or pneumonia. Pleural effusion occurs in 5% to 20% of children. Cutaneous manifestations are common and include macular-papular rash and erythema nodosum. Extrapulmonary symptoms are not uncommon and include bullous myringitis, which supports the diagnosis of mycoplasma.

In sickle cell anemia the mycoplasma infection may be severe and is considered an important cause of acute chest syndrome. Mycoplasma infection also can be severe in Down syndrome, especially in those with congenital cardiac disease. Both mycoplasma and chlamydophila cause exacerbations of asthma in children and adolescents.

The physical examination usually reveals oropharyngeal inflammation. The chest examination findings may be relatively benign, with few crackles and rhonchi, at the same time that a chest radiograph shows significant findings of pneumonia. Wheezing may occur, particularly if the child has asthma.

### **Laboratory**

Cold agglutinins are nonspecific (about 75%), and therefore should not be used to confirm the diagnosis. Mycoplasma immunoglobulin (Ig) M and IgG may be useful to confirm the diagnosis, with sensitivity approximately 98% if both are done. Immunoglobulin M may be negative in the first week of illness, and the presence of IgG may be indicative of past infection. The specificity of *M pneumoniae* IgM detection during an outbreak is higher in those persons 19 years of age or older compared with younger individuals. Immunoglobulin G antibody can

persist for months after infection. It is likely that in the future, diagnosis using PCR will be more readily available clinically, which will expedite the results.

### **Imaging**

Infiltrates are more likely to be bilateral than unilateral. There may be lobar, multifocal, or diffuse disease with reticular infiltrates. Pleural effusions are present in about 20% of the images, and hilar adenopathy is seen in 7% to 22%.

### **Management**

The AAP recommends treatment of mycoplasma pneumonia with macrolide antibiotics, although there are now reports of macrolide resistance. Tetracycline is active, in particular doxycycline, and can be used for adolescents, but not for children younger than 8 years. The newer fluoroquinolones are an alternative treatment.

The lack of cell wall predicts that  $\beta$ -lactams are not effective, nor is trimethoprim. Most cases of CAP improve in a matter of days with no residual findings.

### **Chlamydia trachomatis**

*Chlamydia trachomatis* is an important cause of sexually transmitted infection and trachoma. Although uncommon in the United States, trachoma is the most common cause of blindness in the world. *C trachomatis* causes pneumonia, especially in infants. Approximately 5% to 22% of pregnant women have *C trachomatis* of the cervix, and 30% to 50% of these will show culture evidence of infection. The infection in the newborn is conjunctivitis with or without nasopharyngitis, which in some cases results in neonatal pneumonia.

### **Clinical Features**

Most infants with *C trachomatis* pneumonia have a history of conjunctivitis, nasal stuffiness, and cough with tachypnea. The infant with *C trachomatis* pneumonia is characteristically afebrile. The chest examination reveals scattered crackles; wheezing is absent.

### **Imaging**

The chest radiograph typically demonstrates either a lobar or interstitial pattern.

### **Management**

The recommendation to treat infants with *C trachomatis* pneumonia is erythromycin 50 mg/kg/day divided into 4 doses for 14 days. Azithromycin, 20 mg/kg as a single daily dose for 3 days is an alternative.

### **Chlamydophila psittaci**

*Chlamydophila psittaci* causes psittacosis or ornithosis following exposure to infected birds. Ornithosis is the preferred name because it can be caused by any bird, including parrots, chickens, ducks, turkeys, pigeons, and sparrows. It is transmitted from birds to humans by either direct contact or aerosolization. It is much less common since the imposition of quarantine for a period of 30 days for imported birds and the introduction of bird feed laced with antibiotics.

It is quite difficult to diagnose and it is possible that it is more common than appreciated. The most

common disease is a mild pneumonia, but it can produce a more fulminant illness. There is fever without elevation of the pulse, which is usually associated with fever. The clues to the diagnosis include splenomegaly, a blanching erythematous maculopapular rash, signs of hepatitis, disseminated intravascular coagulation, or meningoencephalitis, any of which may be present.

### ***Chlamydophila pneumoniae***

*Chlamydophila pneumoniae* causes a mild pneumonia or bronchitis in older children, adolescents, and adults. Approximately 50% of young adults have serologic evidence of prior infection. *Chlamydophila pneumoniae* is estimated to cause 10% to 20% of CAP. It is transmitted from person to person by respiratory secretion transfer. The incubation period is approximately 3 to 4 weeks.

Initially there is a URI, and many children have no further symptoms. The symptoms can be prolonged, and the presence of hoarseness and headache is helpful in the diagnosis; fever is uncommon. The physical examination reveals crackles, wheezing, and rhonchi. Even with treatment, *C pneumoniae* tends to respond more slowly than mycoplasma, which may also be a clue to the diagnosis. It also tends to recur if therapy is stopped too early. Azithromycin is effective, and doxycycline can be used in older children and adolescents. Mortality of 9.8% has been reported in children with sickle cell disease.

### **Other Causes of Bacterial Pneumonia**

Tularemia, anthrax, and plague are uncommon bacterial syndromes in which pneumonia may be a prominent feature; they should raise the suspicion of bioterrorism.

## **VIRAL CAUSES OF PNEUMONIA**

Viral infections are the most common cause of symptomatic disease in children. The number of respiratory infections per year may be 5 to 10 or even more, with most being URIs. Most cases of pneumonia are diagnosed clinically, but there is an increasing ability to find an etiologic agent as new biotechnology facilitates the diagnosis of viral infections. As noted previously, secondary bacterial infection occurs in one-quarter to one-third of cases of viral pneumonia. Although immunocompromised children are at higher risk for the opportunistic infections, such as cytomegalovirus, varicella-zoster virus, herpes simplex virus (HSV), and measles, they are also at risk of seasonal pneumonias, including RSV, influenza, and parainfluenza virus. The symptoms of viral pneumonia are similar to those of bacterial pneumonia, although there is less chest pain or rigors with viral pneumonia.

### **Respiratory Syncytial Virus**

Respiratory syncytial virus is the most important cause of lower respiratory infection in the first 2 years of life. By 2 years of age, more than 94% of children will have serologic evidence of RSV infection. During the RSV season, RSV will be the cause of more than 90% of infants hospitalized with bronchiolitis. The differentiation between bronchiolitis and pneumonia can be difficult, so the designation of lower respiratory

tract infection caused by RSV may be easier than trying to define whether there is one or both diagnoses. Infants with RSV pneumonia tend to have less wheezing, less hyperinflation, and more crackles.

The clinical scenario is similar to bronchiolitis, with an upper respiratory prodrome followed by worsening cough and increasing respiratory distress. As noted, wheezing tends to be less prominent and there may be crackles on examination. The radiographic appearance of lobar consolidation (especially right upper lobe) or a bronchopneumonia pattern supports the diagnosis of pneumonia.

Most infants with RSV pneumonia recover in a few days, but a small percentage progress to respiratory failure. Infants younger than 2 months and those with significant respiratory distress or apnea should be hospitalized.

### **Influenza Virus**

The influenza virus is a single-stranded RNA virus that is a common cause of pneumonia, especially in the very young and very old. It occurs in epidemic form in the winter months. Children 2 years or younger and chronically ill children are at more risk for serious illness. Pandemics in the last 100 years include the 1918–1919 Spanish pandemic (influenza virus subtype H1), the 1957 pandemic (subtype H2N2), the 1968–1969 pandemic (Hong Kong subtype H3N2), the Russian pandemic in 1977 (subtype H1N1), and the novel influenza A (H1N1) pandemic of 2009–2010. The incubation period is 1 to 5 days following exposure to the virus.

The presentation of influenza is characteristic with high fever, chills, muscle aches, and headache, although young children may have more nonspecific symptoms. The illness starts as a URI with rhinitis, pharyngitis, and initially nonproductive cough. Young children may also have conjunctivitis and gastrointestinal symptoms. Pneumonia is associated with increasing respiratory symptoms and hypoxemia. Secondary bacterial infection may occur following influenza pneumonia.

Positive A or B influenza virus can be determined by immunofluorescence or hemagglutination techniques, although during the 2009–2010 H1N1 pandemic these tests were not very helpful in diagnosis. Polymerase chain reaction has a higher sensitivity and specificity and is now more readily clinically available, especially for hospitalized children and adults.

Symptoms last for several days and are treated with over-the-counter medications. Aspirin is not indicated because of the association with Reye syndrome.

Oseltamivir (Tamiflu) is approved for oral administration in persons older than 1 year with influenza A or B who have been symptomatic for no more than 2 days. Oseltamivir can be given to infants younger than 1 year with reduced dosage. Although vaccination is the preferred approach for prevention, zanamivir and oseltamivir, with specific age considerations, are recommended by the AAP for prophylaxis of influenza infection. Adamantane (amantadine and rimantadine) resistance emerged in the United States during the 2008–2009 influenza season, and by 2009 most influenza A viruses and all influenza B viruses were noted to be resistant to these agents.

### H1N1 Influenza

Following an outbreak of influenza in Mexico in 2009, the WHO raised the pandemic alert to phase 6, implying a global pandemic. The virus that evolved was a combination of swine, avian, and human influenza genes. The epidemiology was different than in previous pandemics because the risk for severe disease and mortality was highest in pregnant women. In addition, the population aged 5 to 59 years was associated with more severe disease than the very young or very old. On August 10, 2010, the WHO declared an end to the 2009 H1N1 pandemic globally, although they and the Centers for Disease Control and Prevention (CDC) warned that the virus is likely to circulate during subsequent influenza seasons. Through the 2015–2016 influenza season, cases of influenza caused by this strain continued to be identified.

### Human Parainfluenza Virus

Human parainfluenza virus (HPIV) has 4 serotypes: HPIV-1, HPIV-2, and HPIV-3 cause croup; HPIV-1 and HPIV-3 cause lower respiratory tract infection, including bronchiolitis, bronchitis, and pneumonia. Outbreaks of HPIV-3 occur during spring and summer. Almost all children have been infected and, as immunity is short lived, repeated infections occur. Human parainfluenza virus is spread via droplet and fomite exposure.

Morbidity and mortality from HPIV lower respiratory tract infection is uncommon in the United States in immunocompetent hosts. It is a significant cause of mortality in both adults and children with primary immunodeficiency as well as those in developing countries, especially following secondary bacterial infection in malnourished children.

### Adenovirus

Adenovirus is an enveloped DNA virus that causes both upper and lower respiratory infection. Most cases are mild, self-limited URIs. The population at risk for severe disease is the immunocompromised, including the post-transplant patient, especially children who received hematopoietic stem cells or solid organ transplants. Treatment is symptomatic. Cidofovir has been used.

### Human Metapneumovirus

Human metapneumovirus was first described in the Netherlands in 2001. It is in the same family as RSV and HPIV (the Paramyxoviridae family). In the pediatric population the infections are similar to RSV, although the illness tends to be milder and the children tend to be older. The symptoms include rhinorrhea, cough, tachypnea, and fever. The signs include retractions, crackles, and wheeze. The clinical manifestations are similar to RSV bronchiolitis, but pneumonia and respiratory failure may occur.

### Coronavirus

Coronavirus made headlines in 2003 when the severe acute respiratory distress syndrome was the cause of life-threatening pneumonia. The virus quickly spread from China to the rest of the world, affecting 8,000 people in 29 countries, and caused 774 deaths. As a

result of intensive infection control measures, the global transmission was halted in 2003. Several coronavirus strains are associated with upper respiratory tract disease and, less frequently, lower respiratory tract infections like bronchiolitis and pneumonia. It is speculated that subsequent variant strains of coronavirus will cause increased cases of pneumonia in the future, especially in infants and immunocompromised individuals.

### Varicella-zoster Virus

Varicella-zoster virus is a herpesvirus that causes chickenpox and has the potential to reactivate as shingles. Risk factors for varicella pneumonia include high-dose steroids (1–2 mg/kg/day for >2 weeks), malignancy (including leukemia), and other immunocompromised states (including HIV). Varicella pneumonia causes significant mortality and is associated with severe invasive group A streptococcal disease. The viremia is treated with acyclovir, and children with varicella pneumonia should be hospitalized.

### Measles Virus

Measles virus is another member of the Paramyxoviridae family. It causes a febrile illness with morbilliform rash; pneumonia can occur. Children who are unvaccinated, malnourished, or immunocompromised are at risk for severe lower respiratory tract infection.

### Cytomegalovirus

Cytomegalovirus (CMV) is a virus in the herpes group. Cytomegalovirus pneumonia is a major cause of pneumonia in immunocompromised children, including those with transplant, HIV infection, and malignancy. The typical scenario is that 2 to 3 months post-transplant there is cough and fever, and severe dyspnea and hypoxia result. The symptoms are non-specific, and the lung involvement is an interstitial pneumonia. The chest radiograph shows bilateral interstitial infiltrates. Pulmonary symptoms may be accompanied by gastrointestinal disease, especially diarrhea and chorioretinitis. Cytomegalovirus pneumonia may also occur in infants younger than 3 months and can be especially severe in premature infants.

Ganciclovir is used as prophylaxis in transplant patients at risk (eg, a seropositive donor and seronegative recipient). It is also beneficial for symptomatic children with pneumonia.

### Herpes Simplex Virus

Herpes simplex virus infection is also seen in immunocompromised and transplant patients. The highest risk group is those patients that are severely neutropenic or lymphopenic. Pneumonia may result from transmission from the upper to the lower airway or as a result of viremia from oral or genital lesions. Treatment is with acyclovir 5 mg/kg every 8 hours intravenously or 400 mg orally 5 times per day.

Herpes simplex virus pneumonia may also rarely occur as a manifestation of HSV disseminated disease in the neonate. Because of the difficulties in making this diagnosis, mortality can be high unless recognized early in the course of the infection. Acyclovir

therapy and infectious diseases consultation is important in such cases.

## FUNGAL CAUSES OF PNEUMONIA

### *Aspergillus*

*Aspergillus* species are common on decaying material everywhere. There are more than 900 species, but *Aspergillus fumigatus* is responsible for about 90% of infections in humans. They are dichotomously branching septate hyphae. The spores or conidia are small, 2 to 3 microns, and easily inhaled into the lower respiratory tract. There are 3 forms of disease associated with aspergillus: invasive aspergillosis, allergic bronchopulmonary aspergillosis, and aspergilloma within a cavity. This section will discuss pneumonia caused by aspergillus. Opportunistic infections result when children are neutropenic or immunocompromised. Both profound (polymorphs  $<100 \mu\text{L}$ ) and prolonged ( $>12$ – $15$  days) neutropenia carry high risk for developing invasive aspergillosis. It is common post-transplant, in children with cancer, and with CGD.

### Clinical Features

Eighty percent to 90% of children with acute invasive aspergillosis will have pulmonary disease. Nonproductive cough with fever, shortness of breath, blood in the sputum, and pleuritic chest pain are the main symptoms. Twenty-five percent of affected children may have minimal physical signs; others may present with hypoxemia. Chronic invasive pulmonary aspergillosis is associated with diabetes mellitus, CGD, and HIV.

### Diagnosis

Hyphae may be evident microscopically, but this does not prove the diagnosis because other fungi may have a similar appearance. Culture of sputum or bronchoalveolar lavage fluid will not provide a definitive diagnosis because it is important to be aware that these specimens may be positive in those who are colonized with aspergillus. Evidence of invasive aspergillosis is supported by the finding of galactomannan (GM) in these fluids; this test has been approved by the US Food and Drug Administration. The negative predictive value of GM is highly specific; however, GM is not positive in 100% of children with pulmonary aspergillosis. The GM test may be falsely positive in children receiving either piperacillin-tazobactam or ampicillin-sulbactam.

### Imaging

Plain chest radiograph of invasive aspergillosis reveals wedge-shaped infiltrates and cavities, and CT may be helpful for the early diagnosis of invasive aspergillosis. The halo sign, which is ground-glass attenuation surrounding a soft tissue nodule, is characteristic, and cavitation may follow.

### Management

Voriconazole has become the treatment of choice for invasive aspergillosis. Rapid institution of treatment is necessary because invasive aspergillosis can be rapidly progressive. Posaconazole or amphotericin B may be considered if there is a possibility of mucor. In

addition, caspofungin has also been approved for treatment of invasive aspergillosis if there is resistance or intolerance to other therapies. Consultation with infectious diseases is indicated.

### *Candida*

*Candida* species, especially *Candida albicans*, are the most common fungal infections to cause disease in humans. Disease caused by *Candida* species includes cutaneous, gastrointestinal, oropharyngeal (thrush), and vulvovaginal candidiasis. The respiratory tract is frequently colonized with *Candida* species and may result in tracheobronchitis or pneumonia. Invasive candidiasis results from host defects and other risk factors, including CGD, diabetes, and immune deficiency states.

*Candida* pneumonia is associated with disseminated candidiasis, and the lungs are rarely the only organ involved. The most common form is multiple lung abscesses as a result of hematologic spread of *Candida*. The physical signs include fever, dyspnea, and evidence of sepsis. The lung examination is variable, from noncontributory to rhonchi, crackles, and wheeze.

Fluconazole is the treatment of choice for the non-neutropenic child, initially intravenous, and with improvement can be switched to oral. If it is unclear whether there are other molds involved, voriconazole may be a better alternative. With more severe infections and in high-risk children, echinocandins, such as caspofungin, may be a better selection, especially if the infection is nonalbicans, such as *Candida glabrata* and *C. krusei*.

### Blastomycosis

*Blastomyces dermatitidis* is a thermal dimorphic fungus, and the conidia (spores) that convert to yeast are infectious to humans. In the United States, the states most likely to be the site of infection are adjacent to the Mississippi and Ohio rivers and the Great Lakes. The conidia are inhaled and deposited in the lungs. Incubation time is variable but averages 4 to 6 weeks.

### Clinical Features

Blastomycosis is rare in children and results from inhalation of spores. About 50% of infected children will be asymptomatic. Those who are symptomatic have flu-like symptoms with fever, chills, night sweats, weight loss, and myalgia. The pulmonary symptoms include cough and chest pain. There is an acute form as well as a chronic form, which may last 2 to 6 months and is associated with weight loss and cough. Either acute or chronic pulmonary blastomycosis has the potential for a more severe course with life-threatening infection, which may disseminate to the skin, central nervous system, and bone.

### Diagnosis

The sputum is full of polymorphonuclear cells and has a high yield for fungal stain; the fungus grows from culture of sputum, tracheal aspirate, bronchoalveolar lavage, cerebrospinal fluid, and urine. Direct identification of the fungus is possible by experienced personnel. Children who do not expectorate sputum may

need bronchoscopy or lung biopsy to confirm the diagnosis.

### Imaging

The chest radiograph shows infiltrates, reticulonodular pattern, and pleural effusion, and in some cases cavitation is evident.

### Management

For moderate to severe disease, amphotericin B should be used until improvement is noted; then the child can switch to itraconazole to complete a 6- to 12-month course of therapy. For mild to moderate disease, itraconazole should be given to complete a 6- to 12-month course of therapy.

### Coccidioidomycosis

*Coccidioides* species are dimorphic fungi endemic in the soil of the southwestern United States, Mexico, and Central and South America. Inhalation of spores, even a single spore, results in an acute pulmonary infection. It is not spread from person to person. There is increased risk when the soil is disrupted, for example by earthquake or farming, particularly when the soil is dry. The incubation period is 10 to 16 days, although the range is 7 to 30 days.

### Clinical Features

The most important part of the history is the story of travel or residence in an endemic area, and the exposure can be as simple as driving through the area. More than half of those infected will be asymptomatic. If there are symptoms the primary infection leads to a flu-like illness. Symptoms include fever, dyspnea, arthritis, and rash. The rash is characteristically erythema multiforme or erythema nodosum. The primary infection may be followed by disseminated coccidioidomycosis, although this is less common in children than in adults. Most children recover even without treatment. Some children have fatigue that lasts for months.

### Diagnosis

Coccidioidal IgM appears within 1 to 3 weeks of onset of symptoms and lasts for 3 to 4 months.

### Imaging

Chest radiograph findings tend to be nonspecific with infiltrates, hilar adenopathy, and small pleural effusions. A small percentage of children have nodules or cavities early on, and 5% to 10% have persistent pulmonary nodules or cavities. The cavities tend to be thin-walled and resolve spontaneously. On occasion the cavities expand. If they are larger than 6 cm they are at risk for rupture and surgery is indicated.

### Management

Most immunocompetent children do not require treatment, but the following are considerations for treatment:

- Continuous fever for longer than 1 month
- Night sweats for longer than 3 weeks
- Weight loss greater than 10%
- Large (>50% of 1 lung) or bilateral pulmonary infiltrates

- Primary infection during infancy
- Primary infection during pregnancy, especially in the third trimester, or immediately postpartum
- Immunosuppression
- Diabetes mellitus or pre-existing cardiopulmonary disease

Treatment of acute pulmonary coccidioidomycosis includes oral azoles, such as fluconazole. During pregnancy amphotericin B is preferred because the azoles may be teratogenic. Although uncommon in children, those with disseminated disease or progressive fibrocavitary disease may require prolonged treatment up to 1 year.

### Histoplasmosis

*Histoplasma capsulatum* is a dimorphic fungus that is endemic in the central United States and other parts of the world that have warm, humid soil and large populations of migratory birds or chickens. It is the most common pulmonary mycosis of humans, and can occur at any age. The geographic distribution is the central United States, specifically the Ohio and Mississippi river valleys, and it is endemic in Central and South America, the Caribbean, Africa, and Asia.

### Clinical Features

The clinical features of histoplasmosis depend on the size of the inoculum, the immune status of the host, and the presence of lung disease. The exposure increases if there is major disturbance of soil, as with construction projects and proximity to chicken coops, especially those with rotten wood. The incubation period is 9 to 17 days, and the acute illness is characterized by flu-like symptoms of fever, chills, muscle aches, nonproductive cough, and chest pain. The acute symptoms may be mild (lasting less than a week) to severe (lasting 2–3 weeks). There are varied clinical manifestations, again differing with the immune status.

Severe acute pulmonary syndrome results from exposure to a large inoculum and starts with an acute flu-like syndrome, with fever, chills, and myalgias. Pulmonary symptoms develop with cough, dyspnea, and hypoxemia. The chest examination includes diffuse fine crackles with possibly a pleural rub. There may be rapid progression to acute respiratory distress syndrome. Some children develop a single pulmonary nodule in the lung parenchyma, which has the appearance of a coin lesion on chest radiograph. It is usually asymptomatic.

Mediastinal obstructive syndrome results from hilar lymphadenopathy, which may be large enough to compress surrounding structures, including the airway, the great vessels, and the esophagus.

### Diagnosis

Rapid enzyme-linked immunoassays for *Histoplasma* antigen in urine, cerebrospinal fluid, and bronchoalveolar lavage fluid along with serology (immunodiffusion or complement fixation), plus cultures or tissue examination and stains are used for diagnosis.

### Management

Acute pulmonary histoplasmosis that is asymptomatic or mild requires no treatment. If the symptoms

are prolonged for more than 4 weeks, oral itraconazole for 6 to 12 weeks is indicated. If there is severe infection, treatment should be initiated with amphotericin B for 1 to 2 weeks followed by a year of itraconazole.

### **Pneumocystis Pneumonia**

*Pneumocystis carinii* pneumonia led to the abbreviation PCP. *Pneumocystis carinii* was originally classified as a trypanosome and later as a protozoan, and now as a unicellular fungus. It was recently renamed *Pneumocystis jiroveci* because *P. carinii* is not found in humans. The accepted abbreviation is still PCP. Pneumocystis pneumonia is the most common opportunistic infection in children with HIV and is common in transplant patients. The routine use of prophylaxis has reduced the prevalence of PCP.

### **Clinical Features**

The symptoms and signs of PCP are nonspecific, so a high index of suspicion is necessary in children who are HIV infected or immunocompromised, especially if they are not taking prophylactic measures. The symptoms are typically shortness of breath, fever, and nonproductive cough, with chills and weight loss. The signs are tachypnea and tachycardia. Auscultation may reveal some crackles, but often there are no adventitious signs. The main finding supportive of the diagnosis is hypoxemia. The typical radiographic appearance is diffuse bilateral infiltrates extending out from the hilum. In the early stages the chest radiograph may be normal; later there may be pneumatoceles. Pleural effusion is uncommon. High-resolution CT may be helpful, as patchy areas of ground-glass appearance are suggestive, particularly in a child with HIV.

Expectorated sputum usually does not yield a satisfactory specimen; induced sputum production with hypertonic saline is the quickest way to make the diagnosis. Bronchoalveolar lavage is the most common procedure performed. The diagnosis is confirmed by various stains, including silver stains, that show the cysts.

The choice of treatment depends on the degree of hypoxemia. The treatment of choice is trimethoprim-sulfamethoxazole (TS), and oral therapy is used for mild cases, although most children will require intravenous treatment at least at first. Intravenous pentamidine is an alternative choice for treatment, especially if there is a reaction to TS. Duration of treatment should be 21 days for children with HIV and 14 days for patients without HIV, and similar durations should be given based on severity of disease (mild vs severe). Those with severe disease may also benefit from the use of corticosteroids.

Chemoprophylaxis against PCP is indicated for children with HIV and those who are immunocompromised, especially transplant patients and those with both primary and acquired immunodeficiency. The standard regimen is 3 consecutive days per week of oral TS. If this is not tolerated, nebulized pentamidine is an alternative. Infectious disease and pulmonary consultation are recommended.

## **MANAGEMENT OF COMMUNITY-ACQUIRED PNEUMONIA**

A sample algorithm for the management of CAP is shown in Figure 315-1. If the clinical impression of pneumonia is high, it is thought that a bacterial etiology is likely, and antibiotics are indicated. The choice of antibiotic will vary depending on age and organisms that are in the community. The "Evidence-Based Care Guideline for Children With Community Acquired Pneumonia (CAP)" from Cincinnati Children's Hospital Medical Center can be reviewed. Additionally, the Infectious Diseases Society of America in conjunction with the Pediatric Infectious Diseases Society published guidelines for the management of CAP in infants and children older than 3 months.

In children from 2 months to 5 years of age the AAP recommends prescribing high-dose amoxicillin 80 to 90 mg/kg/day for 7 days. As previously noted, 17% to 35% of *S pneumoniae* isolates from CAP in the United States are resistant to penicillin G and 15% are resistant to macrolides, which may indicate an alternative when bacterial pneumonia is suspected. However, resistance to penicillin by *S pneumoniae* is a different mechanism from that of *S aureus* and in most otherwise healthy children can be overcome by higher doses of penicillin, ampicillin, or amoxicillin. For hospitalized children with uncomplicated pneumonia, ampicillin, penicillin or, alternatively, a third generation cephalosporin is preferred. Consultation with infectious disease specialists will assist in this decision.

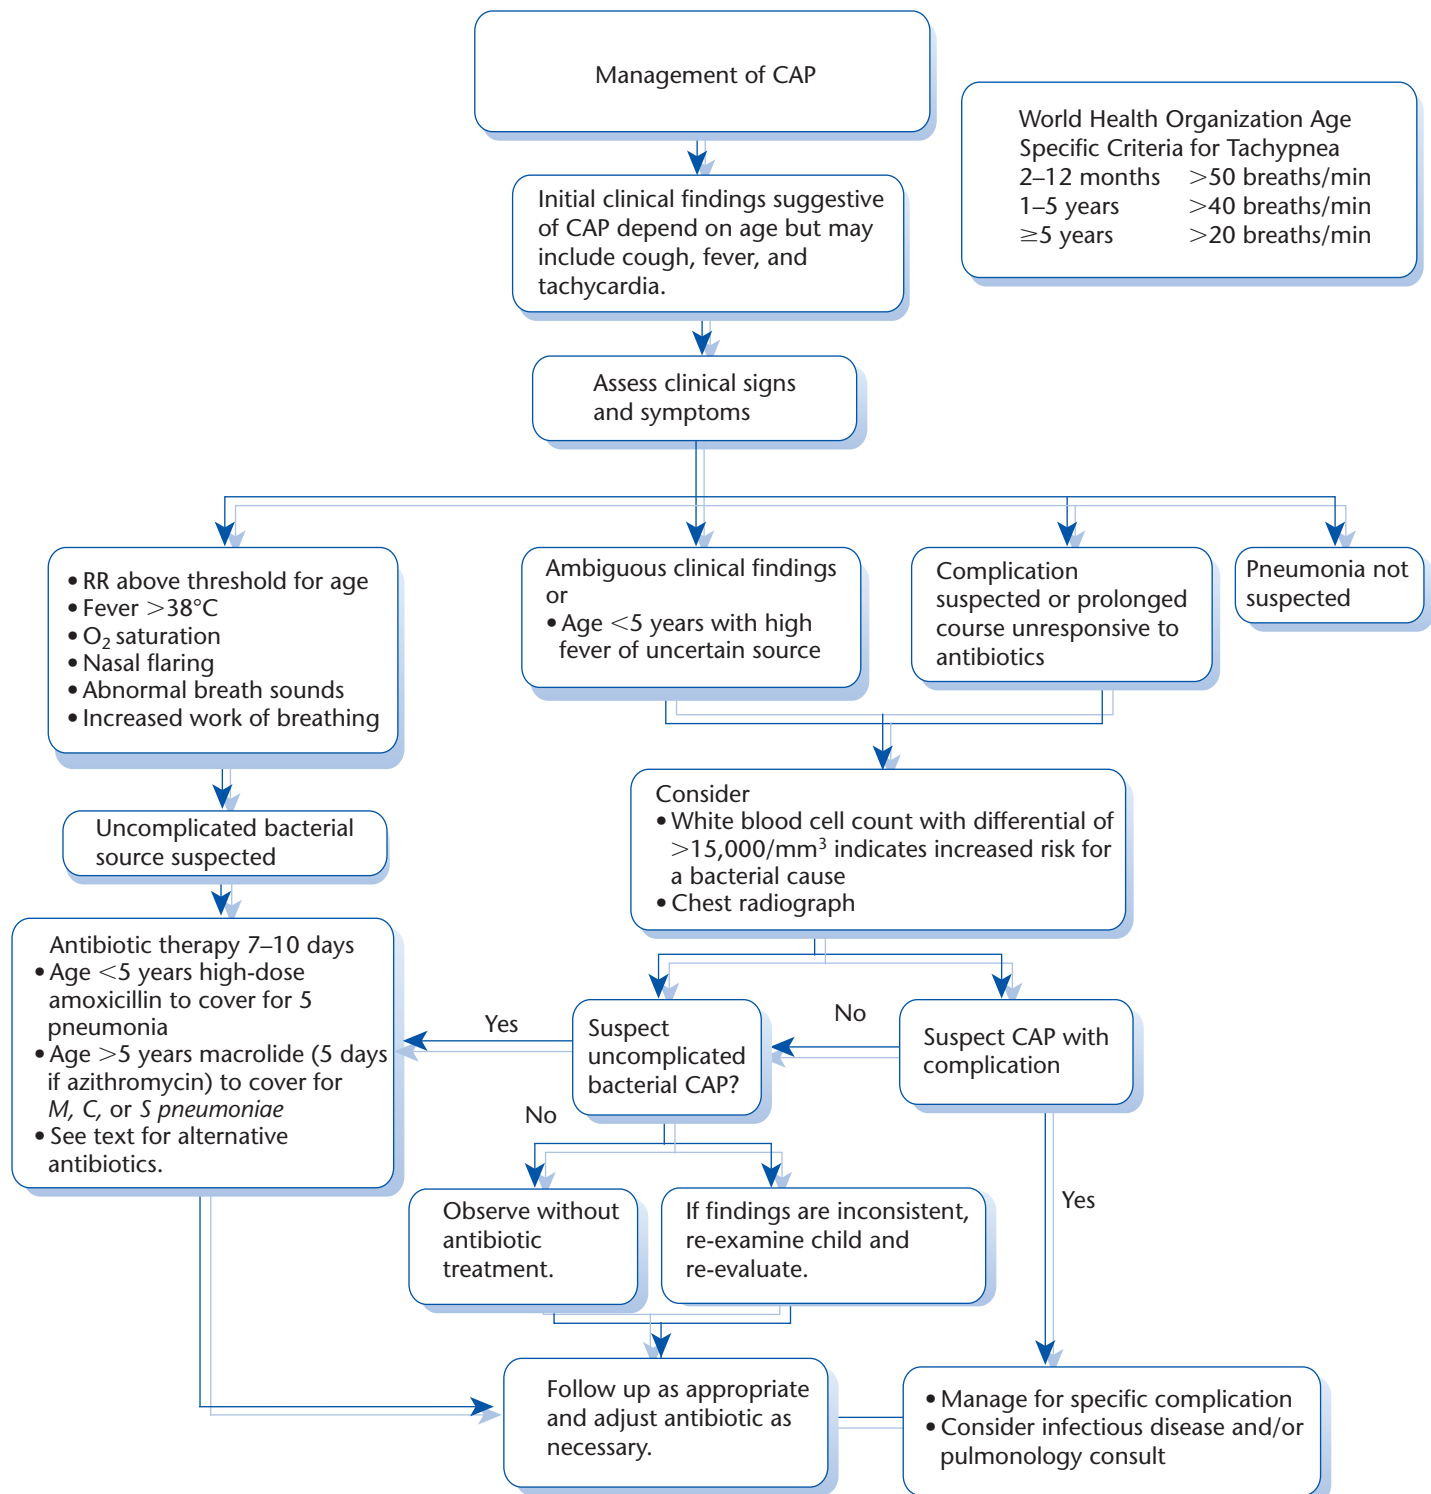

Although mycoplasma infection does occur in children younger than 5 years, a macrolide may not be the best antibiotic choice for empiric treatment at this age, in part because many *S pneumoniae* are now resistant to macrolides or azides. If the child is vomiting or otherwise may be unable to take oral medications, the AAP recommendation is a single initial dose of ceftriaxone prior to attempting oral antibiotics. For children age 5 years and older it is recommended that a macrolide be added to treat CAP in the outpatient setting with either 7 to 14 days of erythromycin or 5 days of azithromycin. Doxycycline for children older than 7 years and levofloxacin alone for older adolescents are alternatives. It is recommended that physicians follow up with children diagnosed with pneumonia within 1 to 3 days.

## **PREVENTION OF PNEUMONIA**

Heptavalent pneumococcal vaccine was recommended in 2000 for children in the United States to reduce the incidence of pneumococcal pneumonia. The original vaccine, which contained 7 serotypes, was highly effective, but two-thirds of the invasive pneumococcal disease was caused by 6 serotypes not included in this vaccine. Subsequently, 13-valent PCV was approved in February 2010 and is recommended for all children from 2 months through 5 years of age.

The CDC recommends that all individuals aged 6 months and older get a seasonal flu vaccine. The seasonal flu vaccine protects against 3 or 4 influenza viruses and varies in composition according to what research indicates will be the most common strains during the upcoming season. Of note, otherwise

**Figure 315-1** Management of community-acquired pneumonia. CAP, community-acquired pneumonia; C, *Chlamydia*; M, *Mycoplasma*; RR, respiratory rate; S, *Streptococcus*.

healthy children aged 2 years and older can also receive either the nasal spray (a live-attenuated influenza vaccine [LAIV]) or the inactivated injectable influenza vaccine (IIV). Children on chronic aspirin therapy should not receive the vaccine because of the

risk of Reye syndrome, and LAIV is not recommended for anyone younger than 2 years of age with chronic health conditions including asthma.

The CDC also recommends that people in contact with certain groups of children get a seasonal flu

vaccine to better protect the child (or children) in their lives from the flu.

The CDC recommends that the following contacts of children receive seasonal influenza vaccination:

- Close contacts of children younger than 5 years (people who live with them), especially those younger than 6 months
- Out-of-home caregivers (nannies, child care providers, etc.) of children younger than 5 years
- People who live with or have other close contact with a child or children of any age with a chronic health problem (asthma, diabetes, etc.)
- All health care workers, to keep from spreading the flu to their patients

Additional considerations are *Haemophilus influenzae* type B vaccine and varicella vaccine.

### WHEN TO REFER

Most children with CAP will not require consultation. If there are complications, such as pleural effusion or prolonged hypoxia, consultation with a pulmonologist may be indicated. If the child has a chronic illness, consultation with the specialist who is involved in their long-term care may be helpful. Consultation with infectious diseases or allergy is indicated when allergies, comorbid conditions, or unresponsiveness to antibiotics are present.

### WHEN TO ADMIT

Children with pneumonia and a chronic illness, for example, if they are immunocompromised, may require hospitalization. If the degree of respiratory distress is significant, if there is hypoxia, or if they seem septic, hospitalization may be required. Currently, validated screening systems do not exist to help predict which children with pneumonia should be hospitalized. Hospitalization is indicated with the following:

- Oxygen saturation consistently less than 90% (definite)
- Suspected sepsis (definite)
- Severe dehydration (definite)
- Inability to drink fluids (possible)
- Moderate or severe respiratory distress (possible)
- Failed outpatient antibiotic treatment (clinical judgment)
- Home circumstance or social situation raises concerns (likely)
- Infants younger than 6 months (unless ideal caretaker)

## Chapter 316

# POSITIONAL DEFORMATIONAL PLAGIOCEPHALY

Deepak M. Kamat, MD, PhD; Ahdi Amer, MD

*Plagiocephaly*, a term with a Greek origin, means *oblique head*. It is used to describe any abnormality in the shape of the head, irrespective of its cause. Posterior deformational plagiocephaly (PDP) is a phenomenon in which flattening of the occiput occurs as a result of mechanical factors that affect the malleable growing skull in utero or during early infancy. It is also referred to as *benign positional molding*, *posterior deformational plagiocephaly*, and *occipital deformational plagiocephaly*. In most patients, the head shape improves with changes in head position, and, in some instances, with helmet therapy. Early recognition and intervention is crucial because early intervention improves outcome. If not treated appropriately, quality of life may be affected.

### PATHOGENESIS

During development, genetic makeup and environmental factors determine the shape of the head. Abnormalities in skull shapes may develop prenatally or postnatally during the first 2 years of life. Whether PDP begins prenatally or is an acquired phenomenon remains controversial. Some investigators think that many infants who develop PDP are born with a mild flattening of the occiput that goes unnoticed in the neonatal period and worsens as the infant continues to sleep on the flat side. Because the infant sleeps in the position of comfort (ie, on the flat side), this condition is termed *positional plagiocephaly*.

A deformity present from birth is usually the result of in utero conditions such as small maternal pelvis,

uterine abnormalities, large baby, multiple gestations, and oligohydramnios or polyhydramnios. Controversy exists regarding the reason for development of PDP in these conditions. Some researchers think that the constrictive and restrictive uterine environment leads to conformational changes in the skull, whereas others think that this environment simply causes severe molding and leads to flattening.

Mechanical pressure on the malleable skull caused by static supine positioning leads to the flattening of the occiput in patients with PDP. Therefore, supine sleeping position, congenital torticollis, prolonged periods in car seats and infant carriers, prematurity, and neurologic conditions such as hydrocephalus are often associated with PDP. The correlation between PDP and supine sleeping positioning is explained by the fact that by the time most infants reach 2 months of age, they have slept for almost 700 hours.

Congenital torticollis is a prime example of the static position of the head in which limited neck motion leads to an asymmetrical flattened occiput involving the torticollis side. However, theories suggest that torticollis develops as a result of PDP. Another example of static head position is among premature infants on ventilator support during which the head is kept in 1 position for prolonged periods. Similarly, cephalohematoma can also lead to the development of PDP on the opposite occipital side.

Hydrocephalus is another risk factor for the development of PDP because of the movement of bones and sutures as a result of volume changes in the cranium and because of the limitations imposed by the draining devices and shunts that result in the infant's head being placed in 1 position for prolonged periods.

Another possible mechanism that may promote favoring 1 side of the head and the development of PDP is the position of the baby's crib in relation to the room's major light source. Infants usually spend much time looking toward the source of light in the room when the baby is in the supine position. Therefore, PDP may develop if the crib is kept in the same location (particularly if it is placed in a corner of the room) and the baby is placed in the same position in relation to the light source.

## EPIDEMIOLOGIC FEATURES

Before 1992, when more than 70% of infants were placed in the prone position during sleep, the incidence of PDP was estimated to be 1 in 300 live births. However, after the *Back to Sleep* campaign was initiated by the American Academy of Pediatrics (AAP) in 1992, the incidence of PDP has been on the rise, with a 2013 study showing that the incidence of PDP is as high as 46.6% among infants between 7 and 12 weeks of age.

PDP is more common on the right side than it is on the left side because of the right-sided sleep position preference of most infants. Almost 85% of neonates have left occipital anterior presentation during birth, which causes pressure on the infant's right occiput and left forehead by the mother's pelvis and lumbosacral spine, respectively.

PDP is more common in boys than it is in girls, probably because male infants have larger heads than

female infants and because boys tend to be less flexible than girls. PDP is also common with primiparity, prolonged labor, and assisted delivery.

PDP is most often first noticed by parents and physicians when the infant is 2 to 3 months of age; however, it can be present at birth. The severity of PDP peaks at 4 months and then resolves gradually over time. In two-thirds of the cases, PDP resolves by 2 to 3 years of age. The resolution is observed to be slow in children with limited head rotation and low activity level.

## DIFFERENTIAL DIAGNOSIS

Distinguishing lambdoid synostosis from PDP in infants with flat posterior plagiocephaly is critical, because the management of these 2 conditions is different. Lambdoid synostosis is a rare condition that occurs in approximately 2% of all cases of craniosynostosis. In patients with lambdoid synostosis, the head is trapezoid shaped; in PDP, conversely, the head is shaped as a parallelogram, with significantly greater protrusion of the forehead on the same side of the occipital flattening as compared with lambdoid synostosis. In PDP, the ear on the flattened side is displaced anteriorly, whereas in lambdoid synostosis, it is displaced inferiorly and posteriorly. In lambdoid synostosis, the posterior basal skull is tilted, with the prominence of mastoid process present on the same side. In addition, the facial deformity seen in patients with PDP is absent or minimal in patients with lambdoid synostosis. Rarely, however, clinically differentiating between PDP and lambdoid synostosis may be difficult.

## DIAGNOSIS OF POSTERIOR DEFORMATIONAL PLAGIOCEPHALY

The diagnosis of PDP in infancy is made primarily based on history and physical examination. Imaging studies are not indicated in most situations. If the infant has a normal, rounded head at birth and, after a few weeks or months, develops an occipital flattening, then the most likely diagnosis is PDP.

Infants with PDP exhibit preferential head position (that is, the infant turns the head only to one side). When the head is viewed from above, a frontal prominence on the same side as the occipital flattening may be observed, and the ear on that side is anterior as compared with the other ear (Figure 316-1). Other craniofacial abnormalities that may be observed on the affected side of infants with PDP are prominent mandibular sulcus with mandibular tilt, uplifted lower helix, smaller ear, and unilateral epicanthal fold. Most infants with PDP have 1-sided occipital bald spots.

The presence of torticollis has to be ruled out in every case of flattened occiput because of its greater association with PDP. Therefore, the primary care physician should perform both passive and active head rotations and check for the tightness of the sternocleidomastoid muscle. The eye on the side of torticollis seems to be incompletely open as a result of the vertical displacement of soft tissues of the cheek. In addition, the mothers of infants with torticollis note that they have difficulty feeding the infants from both breasts because the infants have trouble turning their heads.

**Figure 316-1** This figure shows typical clinical findings in a scalp of an infant with deformational plagiocephaly, namely flattening of occiput on right side with anterior displacement of ear and frontal bossing on the same side and occipital bossing on the opposite side.

Laboratory or imaging studies are not routinely required to confirm the diagnosis of PDP. In the past, skull radiographs were used to rule out lambdoid suture synostosis (Figure 316-2). However, ultrasound examination of the lambdoid suture has also been shown to be useful in ruling out lambdoid suture synostosis. Computed tomography (CT) scans are sensitive in diagnosing synostotic plagiocephaly. Three-dimensional scans are helpful, but the 2D axial views are actually more sensitive in assessing suture patency because they do not demonstrate the volume averaging that the 3D reconprogram creates.

## PREVENTION

In most infants, PDP can be prevented by alternating the supine head position during sleep and by periodically changing the position of the crib in the room to require the infant to look away from the flattened side to see parents and others in the room or to look at the source of light in the room.

The AAP has recommended a certain amount of prone positioning, or *tummy time*, while the infant is awake and being observed. This positioning may help prevent the development of a flat occiput and may also facilitate development of the upper shoulder girdle strength necessary for timely attainment of certain motor milestones. Theories suggest that prone position prevents PDP by correcting or preventing infants' positional preferences.

**Figure 316-2** This figure shows different sutures of the skull and the positions of anterior and posterior fontanelle.

Parents and health care professionals, such as those working in newborn care units, should be educated on different techniques to reduce the risk for development of PDP in infants. Nursing staff and other caregivers should be encouraged to change the head position of a sick newborn whenever possible. Because most caregivers are right handed, much of the care to the baby is provided from the right side of the bed, and thus the baby is placed facing the right side. Caregivers should be encouraged to provide care from the left side of the crib whenever possible and to reposition the infant from head to foot from time to time.

Infants who are breastfed are less likely to develop PDP because, during breastfeeding, alternate head positioning is promoted. However, during bottle-feeding, babies are often held in the left arm, promoting right occipital flattening. Parents should be advised to use alternate arms during each bottle-feeding.

## TREATMENT

Definitive guidelines for the management of PDP have not been developed. However, early treatment is successful in most cases of mild to moderate PDP. Investigators have observed that treatment started after 12 months does not produce significant benefits. Therefore, treating PDP early and effectively is important because uncorrected or improperly treated PDP can lead to psychosocial developmental sequelae.

The initial management of PDP is the same as the prevention measures, which consist of educating parents about changing the infant's head position often. If the infant is found to have torticollis, then parents should be taught to use neck motion exercises

for the infant. The first exercise is used to stretch the sternocleidomastoid muscle and consists of placing 1 hand on the infant's upper chest and rotating the infant's neck with the other hand so the chin touches the shoulder. The head should be held in this position for 10 seconds. The head is then rotated to the other side and held for an additional 10 seconds. In the second exercise, the infant's head is tilted so that the ear touches the shoulder and is held in that position for 10 seconds. The same process is followed on the other side. This exercise stretches the trapezius muscle. The parents should be asked to perform these neck exercises with every diaper change, with 3 repetitions of each exercise. Estimates suggest that an additional 2 minutes are required for these exercises per diaper change. In most cases, with early implementation of repositioning and neck exercises, considerable response is seen over a 2- to 3-month period. The infant should be referred for physical therapy for stretching exercises if these exercises fail to improve torticollis within 2 to 3 months. If no improvement is evident, or if plagiocephaly worsens after 2 months of repositioning and physical therapy, then the infant should be referred to a pediatric neurosurgeon or a craniofacial surgeon for further management.

Skull-molding helmets have been used for reshaping the affected skull. To achieve the desired response, helmets have to be used in the age range of 4 to 12 months because of the malleability of the young infant's skull during this period. Ideally, therapy is begun at 4 to 6 months of age and may be continued until 12 to 14 months of age. Head growth remains normal during helmet therapy, which works by symmetrically shaping the cranial growth. The use of helmets is more beneficial for patients with severe deformity and in infants with mild to moderate severity who are resistant to position changes and physical therapy.

No consensus exists on the use of helmets in infants with positional plagiocephaly. In some studies, better improvement in the skull shape has been observed in infants treated with helmets as compared with that achieved by repositioning alone. Research has shown that repositioning infants may produce improvement in mild to moderate cases similar to that reported with external orthotic devices. Recently, Dutch researchers used 3D whole-head surface scans to compare 70 infants with deformational plagiocephaly (mean age, 4.8 months) who were treated with helmets (23 hours/day) or active repositioning. Children were matched for initial severity of deformity, and treatment duration was determined by parent and physician satisfaction with outcomes (mean duration, 3 months for helmets and 5 months for repositioning). The helmeted group had significantly greater reductions in asymmetry than the infants who were repositioned (maximum reductions, 4.0% vs 2.5%; mean, 0.9% vs 0.5%). In New Zealand, investigators compared head shape and neurodevelopmental outcomes during infancy and at a mean age of 4 years in 129 children with positional head shape deformities who were treated with repositioning techniques. PDP improved or normalized in 87% of children by age 4 without use of a helmet. Also, concerns about head shape

and parental assessment of development improved. Disagreement also exists on the cost effectiveness of helmets in the treatment of PDP. The AAP states that helmets are beneficial in the treatment of PDP after the position changes and exercise have failed. Helmets used for treating PDP are considered to be class II neurologic devices and are regulated by the US Food and Drug Administration. Information on the approved orthotics can be obtained at [www.fda.gov](http://www.fda.gov).

Although surgery is rarely needed to treat PDP, it may be indicated in severe cases in which infants have been presented late for management, thus missing the window of opportunity for success with repositioning, physical therapy, or helmet therapy. Craniotomy does not provide superior results in comparison with physical or helmet therapy as far as a cosmetic outcome is considered. Surgery is also associated with significant morbidity.

## SEQUELAE

The ipsilateral temporomandibular joint is pushed anteriorly in patients with PDP, and, therefore, the mandible develops asymmetrically. The positional and helmet therapies improve the head shape but not the position of the temporomandibular joint or the asymmetry of the mandible. PDP also causes forehead and facial shifts that may lead to asymmetric positioning of the eyes and cause bilateral astigmatism. Fitting corrective glasses on an asymmetric head is also difficult.

Cognitive and psychomotor development has been observed to be mildly delayed in patients with PDP. Whether these delays can be corrected with therapy or whether they are the cause or the effect of PDP is not known. It has also been suggested that decreased prone positioning may be the main factor associated with mild motor delay. Large prospective short-term outcome studies show motor delays, but long-term outcome studies have inconsistent findings.

### WHEN TO REFER

- After position change and physical therapy have failed to correct PDP
- In severe cases
- When the patient who has PDP is older than 12 months
- When lambdoidal craniosynostosis is a possibility

### WHEN TO ADMIT

- Surgical correction of PDP

**Chapter 317****POST-TRAUMATIC STRESS DISORDER**

Judith A. Cohen, MD; David J. Kolko, PhD

Post-traumatic stress disorder (PTSD) is a psychiatric disorder that some children and adolescents develop in response to experiencing or witnessing traumatic events (eg, child abuse; domestic, community, or school violence; traumatic loss; accidents; fires or natural disasters; terrorism or war; traumatic medical conditions or multiple traumas). More than two-thirds of all children experience trauma exposure, with one-third experiencing multiple traumas. The prevalence of PTSD after such events has been estimated based on studies of various types of stressful events, and thus, not surprisingly, the rates vary considerably by type of event. Other characteristics that are related to prevalence are demographics, family characteristics, and research methods. Among the few nationally representative studies, early studies of adolescents and young adults reported overall lifetime PTSD rates of 9.2%. Many children may not meet full criteria for PTSD but still have clinically important PTSD symptoms.

PTSD is often underrecognized, particularly in young children who have difficulty reporting certain symptoms and in those who have experienced traumas associated with shame, secrecy, or stigma, such as sexual abuse, domestic violence, or bullying. Although reliance on parental reports of the child's symptoms greatly improves diagnosis in young children, parents who are themselves traumatized or who are the perpetrators of the child's traumatic experience may not wish to provide accurate reports of children's trauma exposure or symptoms.

Left untreated, childhood trauma and PTSD are associated with serious and long-lasting negative outcomes, including impairments in learning, memory, and academic performance; increased risk for depression, suicide attempts, and completed suicide in adolescence and adulthood; increased risk for substance abuse, self-injury, and risky sexual behaviors; and impaired physical health and immunity, with increased health care use in adulthood. Early chronic interpersonal trauma (child abuse or family violence that often leads to placement disruption) causes particularly severe problems, often affecting attachment and trust. Children who have significant PTSD symptoms without meeting the strict psychiatric criteria of this disorder often have functional impairment comparable to those with the full disorder. However, these outcomes are not inevitable. Effective treatment is available for children with PTSD symptoms. If these children are identified and treated with effective interventions, then PTSD symptoms can remit relatively quickly and cost-effectively and do not return. The most tested treatment leads to reduction of depressive, anxiety, shame, and behavioral difficulties and improvements in social competence and parenting skills, in addition to remission of PTSD symptoms.

Because many traumatized children do not spontaneously report their traumatic experiences or trauma symptoms, pediatricians and other physicians may be in the best position to identify these children and to influence developmental trajectory positively. For these reasons, pediatricians should be aware of the high prevalence of child trauma exposure and be willing and able to assess children for the presence of PTSD symptoms in the primary care setting. This chapter presents basic information about assessing trauma exposure and PTSD symptoms in children and adolescents in the primary care setting, as well as referral sources for evidence-based PTSD treatments.

**COMPONENTS OF POST-TRAUMATIC STRESS DISORDER**

To receive a diagnosis of PTSD, the child must have experienced a traumatic event that qualifies as a serious traumatic stressor. Although the American Psychiatric Association *Diagnostic and Statistical Manual of Mental Disorders (DSM-5)* requires specific criteria for a PTSD-level stressor—that is, that it threatens the child's or significant others' life or physical integrity—a realistic understanding of child development dictates that events that objectively are not threatening to life or physical integrity (eg, disruption of attachment to a primary caregiver) might be perceived in this way by a

young child, particularly if the child fears for the safety of a primary attachment figure, even if this fear is not based in reality. Children's perceptions of threats to their primary caregivers significantly predict the children's PTSD symptoms.

In the new *DSM-5* the 4 core symptom clusters of PTSD are (1) intrusion, (2) avoidance of trauma reminders, (3) negative trauma-related alterations in cognitions and mood, and (4) hyperarousal. To meet full PTSD criteria, children older than 6 years of age must have at least 1 reexperiencing symptom, 1 avoidance symptom, and 2 cognition or mood symptoms and 2 hyperarousal symptoms. Children who are 6 years of age or younger must meet similar symptoms but these are described in developmentally appropriate terms and they must have only 1 intrusion symptom, 1 symptom of avoidance or negative alterations in cognitions, and 2 hyperarousal symptoms. Even if a child does not have enough PTSD symptoms to meet the criteria for a PTSD diagnosis, if the symptoms are of sufficient severity to cause significant distress or functional impairment, then these likely warrant a referral for further evaluation.

Intrusion symptoms occur when upsetting feelings are experienced after memories or reminders of the traumatic event ("trauma reminders") recur. These symptoms may be idiosyncratic and hard for parents and pediatricians to identify. For example, that a child who saw her father shot to death began reliving the shooting in her mind whenever a thunderstorm occurred would not be difficult to understand; the sound of thunder reminded this child of the sound of the gunshots that killed her father. However, many other children's reexperiencing symptoms are less apparent. A child became severely distressed and aggressive after a peer failed to acknowledge his presence in the lunch room. Unknown to the educational staff, this served as a trauma reminder of the child's earlier parental neglect and abandonment. Recognizing these situations as reexperiencing phenomena requires an awareness of the child's traumatic past as well as sensitivity to the wide range of individual trauma reminders. Intrusion symptoms may include the following:

- Recurrent and distressing memories or thoughts of the event, including repetitive play
- Recurrent distressing or frightening dreams, including nonspecific scary dreams in younger children
- Feeling or acting as though the traumatic event is occurring again in the present (flashbacks; rare in younger children)
- Intense psychological distress when reminded of the trauma
- Physiologic reactions to trauma reminders, including upset stomach, headaches, and school refusal

The second PTSD cluster includes avoidance symptoms. Children's trauma reminders are accompanied by strong, upsetting feelings. To escape upsetting feelings when trauma reminders are present in many environments, children may develop avoidance coping strategies. For example, children will try to avoid talking about the traumatic experience or will avoid thinking about it. They will avoid places, people, and situations that serve as trauma reminders. For some children, these avoidant strategies become generalized—that is, they not only

avoid the place where the traumatic event happened but also avoid all similar places. For example, a child who was beaten up on the way to school becomes avoidant of going to school at all. A child who was sexually abused in the bathroom at home is now afraid of all bathrooms and becomes enuretic because the child is unable to use the toilet without becoming overwhelmed with fear. Children who deal with fear through avoidance are reinforcing their fears rather than extinguishing them. These avoidant symptoms include:

- Efforts to avoid thoughts, feelings, or talking about the traumatic event
- Avoiding activities, places, people, or situations that serve as trauma reminders

A new cluster has been included in *DSM-5* which includes negative alterations in trauma-related cognitions (beliefs) and mood. Research shows associations between inaccurate or unhelpful beliefs about trauma experiences (eg, self-blame, believing the world is completely dangerous) and PTSD symptom formation. Negative emotional states (eg, shame, guilt) also are highly predictive of PTSD symptoms. Children older than 6 years must have 2 of the following:

- Inability to remember an important aspect of the trauma
- Persistent and exaggerated negative beliefs or expectations about oneself, others or the world (eg, "I am bad", "No one can be trusted", "the world is completely dangerous")
- Persistent, distorted cognitions about the cause or consequences of the traumatic event(s) that lead the individual to blame himself/herself or others
- Persistent negative emotional state (eg, fear, horror, anger, guilt, or shame)
- Markedly diminished interest or participation in significant activities
- Feelings of detachment or estrangement from others
- Persistent inability to experience positive emotions (eg, inability to experience happiness, satisfaction, or loving feelings)

The fourth PTSD cluster includes hyperarousal symptoms that were not present before the traumatic event. In children who have experienced chronic trauma, such as ongoing domestic or community violence or child abuse, assessing the onset of these symptoms or distinguishing them from other syndromes such as attention deficit/hyperactivity disorder may be difficult. A new item included in *DSM-5* is reckless or self-destructive behavior. Increased arousal symptoms include the following:

- Irritable behavior and angry outbursts (with little or no provocation) typically expressed as verbal or physical aggression toward people or objects
- Reckless or self-destructive behavior
- Hypervigilance
- Exaggerated startle response
- Problems with concentration
- Sleep disturbance (eg, difficulty falling or staying asleep or restless sleep)

To receive a diagnosis of PTSD, a child must have experienced these symptoms for at least 1 month, causing significant clinical distress or functional impairment in social, school, family, health, or another important area of daily living.

## ASSESSING TRAUMA EXPOSURE

Pediatricians who have a favorable relationship with their patients will feel comfortable asking the child directly about possible exposure to a variety of different types of traumas at well-child care appointments. Generally, children and parents should be asked these questions in private, rather than together, because many types of traumas are believed by children or parents to be stigmatizing and shameful or things that should be kept secret within the family. Children may be less likely to disclose such information in the presence of the parent than alone with the pediatrician. Reporting requirements in the case of child maltreatment are discussed elsewhere in this volume, and these guidelines should be followed if the child discloses maltreatment in this context. (See Chapter 367, Physical Abuse and Neglect.) Some general questions designed to elicit information about a child's potential exposure to traumatic events are as follows:

- Has any significant change occurred in the child's life or functioning since the last visit?
- Since the last time the child was seen, has something really scary or upsetting happened to the child or someone in the child's family?
- Has any significant change occurred in the child's behavioral or emotional functioning?
- Has anyone reported or observed any sudden changes in the child's behavior or mood?

The pediatrician is also encouraged to monitor a child's potential exposure to specific traumatic events or experiences. Box 317-1 lists some key domains that should be included in an interview. Self-report instruments are also available for inquiring about trauma exposure. Commonly used exposure instruments include the Traumatic Events Screening Inventory for Children, which can be administered as a self-report instrument, and the UCLA PTSD Index for *DSM-IV*.

## ASSESSING POST-TRAUMATIC STRESS DISORDER SYMPTOMS

When assessing children for the presence of PTSD symptoms, it is common to anchor the symptoms to a specific trauma. However, many children experience multiple traumas, and it is difficult for these children to name a particular trauma as "the worst" or to tie specific symptoms (eg, difficulty sleeping or concentrating) to a particular trauma. It may be best to ask whether the child has any PTSD symptoms related to any traumatic experience. Eliciting PTSD symptoms from traumatized children is a challenging task, particularly when asking about avoidance. Children and parents should ideally be asked about the child's symptoms separately to obtain optimal information. Counting a symptom as present if either the child or the parent reports it (the "OR criterion") significantly improves the rate of accurate diagnosis.

Given all of these requirements, in most pediatric practices, time demands will preclude pediatricians from conducting personal interviews to assess PTSD symptoms. No validated screening instruments are available for *DSM-5* at the time of this writing. The 9-item child self-report Abbreviated UCLA PTSD

### BOX 317-1 Key Domains That Should Be Included in an Interview

- Bad accidents (vehicular, falls, fires)
- Medical trauma, illness, or related procedures (eg, long hospitalization stay, painful procedures)
- Natural disasters (storm, hurricane, blizzard, earthquake, flood, hit by lightning)
- Physical violence (toward child or other, threatened or happened, including bullying)
- Domestic violence (adults fighting, attacking, shooting, stabbing, beating each other up at home)
- Sexual abuse (unwanted touches in private parts, taking pictures, Internet abuse)
- Physical abuse at home (beating, punching, hitting by parent or older sibling)
- Traumatic death (knew or observed someone die—ask about circumstances: was death sudden, shocking, terrifying, gory?)
- Removal from parents or primary caregiver; foster care placement
- Child neglect (eg, caregiver unable to provide for basic needs because of substance abuse or serious mental illness)
- Other scary, frightening events (eg, kidnapping, terrorism)

Index for *DSM-IV* (Figure 317-1) has been used in school settings after disasters such as the September 11, 2001 terrorist attacks with good results and is a reasonable instrument for pediatricians to use in office settings until a *DSM-5* screening tool is available. A score of 20 on the Abbreviated UCLA PTSD Index highly correlates with a diagnosis of PTSD, but because of children's avoidance, underreporting of trauma symptoms, and the general difficulty of eliciting these symptoms, children with scores of 8 or higher also should be referred for evaluation if they have clinically meaningful symptoms or if these are accompanied by functional impairment. If a child with a trauma history is having difficulty getting along with people at school or at home, or if the child has trouble sleeping, eating, or concentrating, then the child should be referred for further mental health evaluation regardless of score on this instrument.

## OTHER TRAUMA-RELATED MENTAL HEALTH PROBLEMS

Childhood traumatic grief (CTG) is another condition that pediatricians should be prepared to recognize and refer for specialized intervention if indicated. CTG occurs in a substantial number of children who lose significant others to death under traumatic (frightening, unexpected) circumstances. Children with CTG get stuck on the traumatic circumstances of the loss and are unable to move through the typical stages of grieving. They may seem less sad than children who are mourning in a more usual fashion because they

1. I get upset, afraid, or sad when something makes me think about what happened.	<b>None</b> <input type="checkbox"/> 0	<b>Little</b> <input type="checkbox"/> 1	<b>Some</b> <input type="checkbox"/> 2	<b>Much</b> <input type="checkbox"/> 3	<b>Most</b> <input type="checkbox"/> 4
2. I have upsetting thoughts or pictures of what happened come into my mind when I do not want them to.	<b>None</b> <input type="checkbox"/> 0	<b>Little</b> <input type="checkbox"/> 1	<b>Some</b> <input type="checkbox"/> 2	<b>Much</b> <input type="checkbox"/> 3	<b>Most</b> <input type="checkbox"/> 4
3. I feel grouchy, or I am easily angered.	<b>None</b> <input type="checkbox"/> 0	<b>Little</b> <input type="checkbox"/> 1	<b>Some</b> <input type="checkbox"/> 2	<b>Much</b> <input type="checkbox"/> 3	<b>Most</b> <input type="checkbox"/> 4
4. I have trouble going to sleep, or I wake up often during the night.	<b>None</b> <input type="checkbox"/> 0	<b>Little</b> <input type="checkbox"/> 1	<b>Some</b> <input type="checkbox"/> 2	<b>Much</b> <input type="checkbox"/> 3	<b>Most</b> <input type="checkbox"/> 4

6. I have trouble concentrating or paying attention.	<b>None</b> <input type="checkbox"/> 0	<b>Little</b> <input type="checkbox"/> 1	<b>Some</b> <input type="checkbox"/> 2	<b>Much</b> <input type="checkbox"/> 3	<b>Most</b> <input type="checkbox"/> 4
7. I try to stay away from people, places, or things that make me remember what happened.	<b>None</b> <input type="checkbox"/> 0	<b>Little</b> <input type="checkbox"/> 1	<b>Some</b> <input type="checkbox"/> 2	<b>Much</b> <input type="checkbox"/> 3	<b>Most</b> <input type="checkbox"/> 4
8. I have bad dreams, including dreams about what happened.	<b>None</b> <input type="checkbox"/> 0	<b>Little</b> <input type="checkbox"/> 1	<b>Some</b> <input type="checkbox"/> 2	<b>Much</b> <input type="checkbox"/> 3	<b>Most</b> <input type="checkbox"/> 4
9. I feel alone inside and not close to other people.	<b>None</b> <input type="checkbox"/> 0	<b>Little</b> <input type="checkbox"/> 1	<b>Some</b> <input type="checkbox"/> 2	<b>Much</b> <input type="checkbox"/> 3	<b>Most</b> <input type="checkbox"/> 4

**Figure 317-1** Abbreviated UCLA Post-traumatic Stress Disorder Reaction Index for *DSM-IV*. (Derived from Steinberg A, Brymer MJ, Decker KB, et al. University of California PTSD reaction index. *Curr Psychiatr Rep*. 2004;6:96-100.)

develop PTSD symptoms of intrusion, avoidance, cognitive and mood changes or hyperarousal. For example, these children may not talk about the deceased person, or seem detached from current caregivers and friends; or they may become easily angered and irritable when others want to reminisce about the person who is gone. Children who lose primary attachment figures as a result of causes other than death (eg, termination of parental rights because of parental substance abuse or maltreatment) may also develop CTG. The pediatrician can be of help to the child and family by recognizing the signs and presentation of CTG and educating the family about this condition.

Additionally, pediatricians should be aware that PTSD is not the only, or even the most common, outcome in children after trauma exposure. PTSD most typically co-occurs with other difficulties, such as depression, anxiety, and behavioral problems. Consequently, the pediatrician may have to include other assessments or instruments to evaluate these potential comorbidities. In some cases, parents initially identify other clinical concerns that may relate to the child's recent exposure to traumatic events. Children may develop these problems in the apparent absence of PTSD symptoms as well, and substance abuse, self-injury,

problems in relationships, and serious behavior problems (eg, severe aggression, sexual behavior problems) are common sequela of traumatic experiences, particularly child abuse and domestic violence. Current PTSD diagnostic criteria may not best describe the multiple effects trauma has on children, particularly after early complex trauma exposure.

## MAKING REFERRALS TO SPECIALIZED MENTAL HEALTH SERVICES

As noted previously, pediatricians should refer children with scores higher than 8 on the Abbreviated UCLA PTSD Index for specialized mental health evaluation. Pediatricians should be aware that, in addition to PTSD symptoms, additional risk factors exist for developing PTSD and other mental health difficulties after traumatic exposure. These risk factors include female sex; more frequent or intense exposure to the traumatic event; having a preexisting anxiety disorder; lack of parental or other support; parental history of PTSD, anxiety or depression, including parental PTSD related to the index trauma; and past trauma exposure. Genetic factors also are emerging as a significant risk for developing PTSD. Children who have

several of these risk factors may need more prompt mental health referrals or closer pediatrician follow-up (or both) after exposure to traumatic life events. Pediatricians may be particularly well placed to follow-up on such children and to monitor them for the later emergence of mental health difficulties.

Effective treatment is available for children who have significant PTSD symptoms, and with optimal interventions, most children are able to recover in as few as 8 to 12 treatment sessions, although children with more complex presentations may need somewhat longer treatment. (See Tools for Practice at the end of the chapter for resources.) Evidence-based treatments for PTSD in children include Trauma-Focused Cognitive Behavioral Therapy (TF-CBT, [www.musc.edu/tfcbt](http://www.musc.edu/tfcbt)); Child-Parent Psychotherapy, a dyadic treatment for young children (<8 years old) and a primary caregiver; and Cognitive Behavioral Interventions for Trauma in Schools, a group treatment for school settings. Descriptions of additional effective and promising practices for pediatric PTSD are available at the National Child Traumatic Stress Network, ([nctsn.org/resources/topics/treatments-that-work/promising-practices](http://nctsn.org/resources/topics/treatments-that-work/promising-practices)).

Most children are remarkably resilient in the face of trauma and do not go on to develop PTSD. However, many children exposed to trauma may experience clinical or subclinical PTSD, with or without symptoms that interfere with their functioning or cause impairment in other domains such as those described earlier. Improvements in such clinical problems have been reported among physically abused children by using Parent-Child Interaction Therapy, Alternatives for Families: Cognitive-Behavioral Therapy, and Combined Parent-Child Cognitive Behavioral Therapy.

In terms of specific efforts that can be made in the office, the pediatrician is in a unique position to promote an initial response to the child who has experienced traumatic events and who exhibits PTSD symptoms. Opportunities to observe the child during routine physical examinations provide both observational and physical evidence that may be relevant to the identification of traumatic exposure and symptoms. These impressions may be confirmed through parental interview when questions about the child's experiences and the timing of any recent or sudden reactions to these events can be ascertained. The pediatrician may also be in a position to work toward preventing PTSD by noting when children seem to be at risk for traumatic exposure or experiences. Potential high-risk scenarios that may be reported by the family include sudden and frequent moves, major disruptions in caregiving environment or caregiver functioning or status, reports of increased frustration or physical force during child management or disciplinary interactions, exposure to or knowledge of age-inappropriate sexual activities, sudden changes in a child's reactions to a caregiver, exposure to drugs and alcohol, and spending a lot of time with nonbiologically related men. Certainly the pediatrician can offer advice regarding steps that may minimize a child's exposure to high-risk situations and encourage parents to monitor and promote child safety, both in and out of the home.

## SUMMARY

Pediatricians are in a critical position to recognize, respond to, and refer traumatized children. The pediatrician may be the first adult or professional to learn about a child's potential exposure to traumatic events or to obtain evidence consistent with this clinical impression. Consequently, the pediatrician may be an initial responder in terms of understanding and addressing PTSD in children. An understanding of the material described in this chapter may provide the pediatrician with some of the basic tools to assess and treat the traumatized child.

## Chapter 318

# PRADER-WILLI SYNDROME

Eileen Dolan, MD; Susan Wiley, MD

Prader-Willi Syndrome (PWS) is a complex genetic syndrome characterized by extreme hypotonia and failure to thrive during infancy, childhood-onset hyperphagia and obesity, unique behavioral characteristics, and cognitive impairment. Hypogonadism, short stature, small hands and feet, and characteristic facial features are also commonly present in individuals with PWS. Many of the manifestations of PWS seem to be related to insufficient functioning of the hypothalamus. However, the nature of the deficiency has not yet been identified.

In 1956, endocrinologists Prader, Labhart, and Willi first described PWS, and the accuracy of their initial findings later helped to form the diagnostic criteria. Accurate and reliable molecular genetic testing has subsequently been developed and is now widely available. Although the diagnostic criteria continue to help identify appropriate individuals for testing, the gold standard for diagnosing PWS is molecular genetic testing. Because strict clinical criteria are not necessary for diagnosis, suggested new criteria have been developed to prompt DNA testing (see Table 318-1).

PWS has been the subject of many genetic breakthroughs. It was the first known microdeletion syndrome identified by high-resolution chromosome analysis. Through this method, it was discovered that PWS results from a deletion in the proximal long arm of chromosome 15.

PWS was also the first known human genomic imprinting disorder. Genomic imprinting is an

inheritance process in which genes are expressed based on only 1 allele, in a parent-of-origin manner. This differs from most cases of inheritance, whereby gene expression occurs from 2 alleles, 1 inherited from each parent. Genomic imprinting is an epigenetic process, meaning that modifications are made to the structure of the DNA, but the DNA sequence is not changed.

In unaffected individuals, the maternally derived genetic material on the critical region of chromosome 15 is inactivated through the process of hypermethylation. This leaves only the paternal genes to be expressed. PWS results from the loss of the paternally derived genetic material in the 15q11-q13 region. The loss of maternal genes in this same area results in Angelman syndrome.

**EPIDEMIOLOGY**

The prevalence of PWS has been reported to be between 1 in 15,000 and 1 in 30,000 people. This may be an underestimate, however, because diagnosis may be delayed in many individuals. The syndrome occurs in both males and females and in individuals of all races. PWS is the most common known genetic cause of obesity.

The risk for recurrence of PWS varies with the underlying genetic mechanism. In general, the recurrence risk is less than 1%, but it can be significantly elevated in rare cases. As a result, after an individual is diagnosed with PWS, genetic counseling should be offered to the family to determine the risk for recurrence in future pregnancies.

**ETIOLOGY**

PWS results from the loss of the paternally derived genes from the proximal arm of chromosome 15. There are 3 known ways in which this can occur: deletion in the paternally contributed chromosome, maternal uniparental disomy, and an error in the imprinting process.

**Deletion in Paternally Contributed Chromosome**

More than 70% of the cases of PWS result from a deletion of paternal genetic material on chromosome 15, between the bands 15q11 and 15q13. The deletion is

**Table 318-1** Criteria to Prompt DNA Testing for Prader-Willi Syndrome

AGE AT ASSESSMENT	FEATURES SUFFICIENT TO PROMPT DNA TESTING
Birth to 2 yr	Hypotonia with poor suck
2–6 yr	Hypotonia with history of poor suck
	Global developmental delay
6–12 yr	History of hypotonia with poor suck (hypotonia often persists)
	Global developmental delay
13 yr through adulthood	Excessive eating (hyperphagia; obsession with food), with central obesity if uncontrolled
	Cognitive impairment; usually mild intellectual disability
	Excessive eating (hyperphagia; obsession with food), with central obesity if uncontrolled
	Hypothalamic hypogonadism or typical behavior problems (including temper tantrums and obsessive-compulsive features)

From Gunay-Aygun M, Schwartz S, Heeger S, et al. The changing purpose of Prader-Willi syndrome clinical diagnostic criteria and proposed revised criteria. *Pediatrics.* 2001;108(5):e92.

usually sporadic, and the recurrence rate is less than 1%. Recurrence increases in the rare cases of chromosomal translocation in the father. Paternal testing should be offered to rule out chromosomal rearrangement and to determine the recurrence risk.

### Maternal Uniparental Disomy

Prader-Willi syndrome was the first identified syndrome resulting from maternal uniparental disomy (UPD). Maternal UPD accounts for approximately 28% of cases of PWS. In UPD, an individual receives two copies of a chromosome from one parent and no copies from the other parent. This may not be problematic when genes are typically expressed. However, it could lead to the loss of active copies of genes that have undergone genomic imprinting, as in the case of PWS. In this case, both copies of chromosome 15 are inherited from the mother, and the active and imprinted paternal genes are not present.

Recurrence risk is usually less than 1% in maternal UPD. The presence of a Robertsonian translocation in either parent can increase the risk, and parental testing is warranted.

### Error in Imprinting

Less than 2% of cases of PWS result from an error in the imprinting process. The paternally derived genes are present, but they are not expressed because of the imprinting abnormality. Nearly all known cases of family recurrence of PWS originate from an imprinting error. Recurrence rates in this category can be as high as 50% when there is a microdeletion in the imprinting center. Most imprinting defects, however, involve an epigenetic mutation. In this group, the recurrence rate is less than 1%.

Many genes have been identified in the region of the deletion in PWS, but the gene functions and mechanisms of action are still being studied.

## DIAGNOSIS

### Signs and Symptoms

#### Physical Characteristics

Characteristic facial features of PWS are initially subtle and may be difficult to appreciate during infancy. As the child grows, the facial features and body habitus become more evident. The common physical findings include the following:

- Almond-shaped eyes
  - Small-appearing mouth with thin upper lip
  - Down-turned corners of the mouth
  - Narrow bifrontal diameter
  - Small and narrow hands and small feet
  - Hypopigmentation (fair skin, eyes, hair) in about one-third of individuals
  - Genital hypoplasia
  - Centrally distributed obesity
  - Short stature
- (See Figure 318-1)

#### Hypotonia and Feeding Difficulties

The most common presenting sign of PWS in infancy is severe central hypotonia. The consistency of this finding has led to the recommendation that all infants

**Figure 318-1** (A) Facial features and (B) obesity in a male with Prader-Willi syndrome. (From Lyons MJ. *Specific genetic conditions*. In: Saul RA, ed. *Medical Genetics in Pediatric Practice*. Elk Grove Village, IL: American Academy of Pediatrics; 2013:175–234.)

with persistent hypotonia be tested for PWS. The hypotonia is prenatal in onset, resulting in decreased fetal movements, abnormal fetal position, and increased occurrence of cesarean delivery. The infant may seem floppy, have a weak cry, and exhibit decreased arousal. Infants with PWS often have a poor suck, leading to problems with feeding. This, combined with lack of awakening to feed, often results in

failure to thrive. The hypotonia gradually improves with age, but most adults remain mildly hypotonic with decreased muscle bulk and tone.

### **Obesity**

PWS is the leading known genetic cause of obesity. As the central hypotonia of infancy becomes less severe, feeding difficulties resolve, and excessive food intake begins. Between 1 and 6 years of age, children with PWS demonstrate hyperphagia and have an insatiable appetite. Individuals develop obsessive behavior surrounding food, including food-seeking behavior, hoarding, stealing, and eating undesired food, such as garbage, frozen food, or spoiled food.

Individuals with PWS have a decreased need for caloric intake owing to a low metabolic rate and less mean muscle mass. The combination of decreased caloric need, hyperphagia, and lack of satiety makes obesity a problem that is difficult to prevent. Obesity is the major cause of morbidity and mortality in PWS and often leads to secondary conditions, including cardiopulmonary compromise, sleep apnea, type 2 diabetes mellitus, and hypertension.

### **Hypogonadism**

Hypogonadism with genital hypoplasia is present during infancy but may become more apparent as the child grows. In males, this may present as scrotal hypoplasia, cryptorchidism, and a small penis or testes for age. Genital hypoplasia is present but difficult to assess in females.

Hypogonadism becomes more apparent in adolescence because of abnormal and incomplete pubertal development. Precocious puberty is uncommon, but precocious adrenarche has been reported. Females usually exhibit oligomenorrhea or amenorrhea, and males have scant body hair and poor voice change. Adolescents lack the pubertal growth spurt, resulting in short stature. An additional contributor to the short stature is the deficiency of growth hormone and insulin-like growth factor 1.

### **Sleep Disturbance**

Sleep-disordered breathing is a common occurrence in PWS. Obesity contributes to obstructive sleep apnea, but sleep is abnormal even in the absence of obesity. Excessive daytime sleepiness, abnormal circadian rhythm in rapid eye movement sleep, abnormal arousal, and central sleep apnea have all been reported.

### **Musculoskeletal Problems**

Hip dysplasia is seen in about 10% of individuals with PWS. Scoliosis is common and can develop at any time during childhood. Kyphosis also frequently occurs and usually develops in adolescence or early adulthood. Osteoporosis is common in adults with PWS and may be the result of hypotonia, low calcium intake, hypogonadism, and growth hormone deficiency.

### **Developmental Delay or Intellectual Disability**

Early developmental milestones are delayed in children with PWS. The average age of sitting is 12 months and of walking is 24 months. Language milestones are delayed as well, with first words reported from

18 months to as late as 6 years. Articulation difficulties are also common.

Intelligence testing has revealed a range of intelligence from low-normal to severely impaired. Most individuals with PWS function in the range of mild intellectual disability. Relative strengths include visual-spatial skills, reading, expressive vocabulary, and long-term memory. Some individuals display exceptional skills with jigsaw puzzles. Weaknesses are seen in sequential processing and short-term memory.

### **Behavior**

Individuals with PWS have unique behavioral characteristics, including temper tantrums, stubbornness, obsessive-compulsive behaviors, and inflexibility. Behavior difficulties often begin around the age of 3 to 4 years and often are related to the cravings for food. Individuals may be manipulative, lie, steal, and become aggressive in their quest for food. Children are persistent and often clever in obtaining food, so parents need to be diligent to prevent hyperphagia.

Obsessive-compulsive characteristics are common, and individuals are often routine oriented with little tolerance for change. Organizing possessions, insistence in routines, hoarding of food and other objects, skin picking, and repetitive behavior are often seen. Approximately 25% of individuals with PWS have been diagnosed with an autism spectrum disorder. Individuals with maternal UPD have a higher rate of autism diagnoses. About 5% to 10% of individuals with PWS develop psychosis in early adulthood.

### **Additional Findings**

Ophthalmologic findings including strabismus, refractive errors, and hyperopia are often present in PWS. Decreased saliva volume is quite common and leads to dry mouth and a possible increase in dental caries. Saliva often becomes thick and viscous, which may contribute to articulation difficulties. Additional findings, including altered temperature perception, high pain threshold, and high vomiting threshold are commonly present and are thought to be related to abnormalities in hypothalamic functioning.

### **Differential Diagnosis**

The differential diagnosis can vary depending on the age of diagnosis. In infancy, the differential diagnosis includes other disorders that present with hypotonia, feeding difficulties, or failure to thrive, such as spinal muscular atrophy, congenital myotonic dystrophy type 1, Angelman syndrome, botulism, and additional neuromuscular or genetic disorders.

In childhood, the differential diagnosis includes conditions that present with intellectual disability and obesity. Some examples include fragile X syndrome, Bardet-Biedl syndrome, Alstrom syndrome, Cohen syndrome, Börjeson-Forssman-Lehmann syndrome, and Albright hereditary osteodystrophy.

### **Diagnostic Approach**

If PWS is suspected based on the clinical criteria, the diagnosis should be confirmed by genetic testing. The order of testing may vary, depending on previous studies and availability of tests. As a result of rapid advances

in technology, referral to a clinical geneticist may be appropriate and may allow more targeted genetic testing.

DNA methylation is usually the first step in testing because it detects 99% of cases of PWS. If biparental inheritance is identified, PWS is ruled out. If methylation studies detect only maternal alleles, PWS is confirmed. For genetic counseling purposes, it is recommended that testing continue until the specific genetic cause of PWS is known. After PWS is confirmed by methylation studies, fluorescence in situ hybridization, UPD studies, and sequence analysis can then be completed to determine the specific cause (deletion, UPD, or imprinting error).

## MANAGEMENT

A multidisciplinary approach should be used in the management of an individual with PWS. The treatment team often includes medical physicians, psychologists, dietitians, nurses, and therapists, with the primary care pediatrician overseeing and coordinating care. Because of the unique characteristics and complications of the syndrome, subspecialists in genetics, endocrinology, development and behavior, and pulmonology should be part of the care team. Genetic counseling and referral to parental support groups should occur at diagnosis.

### Hypotonia and Feeding

Because of the marked hypotonia and ensuing feeding difficulties, adequate nutrition and growth are the major focus of treatment in infancy. Gavage feeding or the use of a special nipple can compensate for the hypotonia and poor suck. Because infants have a decreased state of arousal, a feeding schedule should be created, and the infant should be woken up to be fed. Fats are necessary for the development of the nervous system and should not be limited in infancy. The infant's height and weight should be plotted on a growth curve monthly to monitor progress. A dietitian is helpful in monitoring adequate caloric intake, with a goal of keeping the infant between the 50th and 75th percentiles on the weight-for-length curve.

### Obesity

The transition to hyperphagia and obesity begins in early childhood, so healthy eating habits should be taught from an early age. No medications have been successful in controlling the appetite of an individual with PWS. As a result, weight should be managed with the combination of a restrictive diet, limited access to food, exercise, and behavioral techniques.

Restrictive diets are often started around preschool, and the child's weight should be frequently assessed to guide further recommendations. Detailed food logs are useful for the family and allow professionals to calculate caloric intake. Individuals with PWS should take a daily multivitamin and calcium and vitamin D supplements to compensate for suboptimal intake resulting from the restrictive diet.

Access to food should be limited, and locks should be placed on the refrigerator, cabinets, and garbage cans. Consistent daily schedules around meals and exercise and the use of positive reinforcement with a

token economy may increase compliance with dietary restrictions. Behavioral techniques are also helpful in initiating and maintaining an exercise program. Thirty to 60 minutes of physical activity is recommended on a daily basis.

### Hypogonadism

Males should be evaluated for cryptorchidism, with a referral for surgical intervention when appropriate. Hormone replacement therapy may be considered in the pubertal years and should be discussed with an endocrinologist. Estrogen replacement in females may be beneficial for bone density.

### Growth Hormone

Growth hormone replacement is approved for use in children with PWS, and stimulation testing is not required. The age for starting growth hormone replacement remains controversial, and it usually begins in early childhood. However, studies have shown benefits with starting replacement therapy at 6 months to 1 year of age. Individuals should be referred to an endocrinologist at the time of diagnosis, and discussions of growth hormone replacement can start early on. Growth hormone replacement has been shown to improve childhood growth, lean body mass, and adult height and may have an effect on overall development when started early.

Cases of sudden respiratory death have been reported in children with PWS while being treated with growth hormone. These individuals had a history of significant obesity and pre-existing respiratory or other contributing complications. The deaths were not clearly related to growth hormone replacement, but great care should be taken when initiating therapy. A sleep study and respiratory evaluation are often recommended, and obstructive sleep apnea should be treated before starting replacement therapy. Individuals should be screened for diabetes, hypothyroidism, and scoliosis (with radiograph) before initiation and during the course of growth hormone replacement.

### Sleep

Sleep studies and ear-nose-throat evaluations should be performed if there are concerns about sleep-disordered breathing to determine an obstructive versus central etiology. This is especially important when considering growth hormone initiation because obstructive sleep apnea increases the risks involved in growth hormone replacement.

### Musculoskeletal

Infants should be evaluated for hip dysplasia and scoliosis, and imaging studies and referrals should be made as appropriate. A physical examination for scoliosis is less accurate in obese individuals. Therefore annual radiographs of the spine should be considered to monitor changes in curvature. Individuals with high body mass index values are at increased risk for developing kyphosis. The management of scoliosis and kyphosis may include bracing or surgery (as in the general population). Individuals should be closely monitored for progression of scoliosis during growth hormone therapy.

### Development and Behavior

An early intervention referral is recommended in infancy because of problems associated with hypotonia, motor delays, and language delays. As children are transitioned into school, an education plan should be developed. Psychoeducational testing is recommended to assess individual strengths and weaknesses. Continued therapy, classroom aides, behavior plans, and supervised lunches should all be discussed with the educational team.

Children with PWS often respond well to structured environments and schedules. Limits should be set and consistently enforced starting at an early age. A specialist in development and behavior can help the family set appropriate limits and construct behavior plans. Early limit setting can help prevent more severe behavior problems in the future.

Children with PWS often respond well to positive reinforcement and the use of a token economy. Skin

picking can be quite difficult to treat, but behavioral strategies should be used, with reinforcement for alternative behaviors. When obsessive traits, tantrums, and food-seeking behaviors continue to be problematic, children and their parents often benefit from behavior counseling. Psychopharmacologic agents may be considered. Children should be referred to a psychiatrist if they exhibit signs of psychosis, such as hallucinations, behavior changes, or disorientation.

### Specialists

Table 318-2 provides guidance about when it is appropriate to refer a child with PWS to a specialist.

## ONGOING CARE

### Routine Medical Care

Clinical screening for scoliosis and kyphosis at routine health care visits is recommended. Radiographs should be ordered as needed.

**Table 318-2** When to Involve Specialists in Management of Children With Prader-Willi Syndrome

SIGN OR SYMPTOM	APPROPRIATE REFERRALS
<b>AT DIAGNOSIS</b>	Genetics Endocrine Early intervention programming, school programming
<b>FEEDING/GASTROINTESTINAL</b>	
Poor feeding/suck (infancy)	Dietitian, speech therapist (feeding support)
Food seeking, hyperphagia (early childhood and beyond)	Specialized behavioral therapy for food seeking
Abdominal pain, vomiting, anorexia	Urgent medical workup, especially for gastric necrosis
<b>ENDOCRINE</b>	
Weight gain	Pediatric endocrinology
Growth hormone deficiency	Surgical referral for cryptorchidism
Glucose intolerance	
Delayed puberty	
Hypogonadism	
<b>VISION</b>	
Strabismus (monitor eye alignment)	Ophthalmologist knowledgeable in pediatric conditions
Failed vision screen	
<b>DENTAL</b>	
At higher risk for caries because of decreased saliva production	Referral to dentist accustomed to working with children with delays Reinforce good dental hygiene
<b>SLEEP</b>	
High risk for sleep disturbances, obstructive and central sleep apnea	Monitor for sleep problems Refer for sleep study as indicated by history and before growth hormone initiation
<b>MUSCULOSKELETAL</b>	
Hip dysplasia	Newborn hip examination with appropriate referrals based on findings
Scoliosis (any age)	Monitor for scoliosis and kyphosis at visits (direct visual inspection and scoliometer); refer for radiographs, orthopedic care as indicated. Imaging recommended before starting growth hormone, and annually in obese individuals
Kyphosis (in adolescence)	
<b>DEVELOPMENT/BEHAVIOR</b>	
Developmental delay, cognitive impairment	Early intervention programming
Language delay	School programming
Food hoarding	Developmental-behavioral pediatrician or psychologist or child psychiatrist
Obsessive-compulsive features	depending on issues and community resources
Skin picking	
Autism spectrum disorder	

Eyes should be evaluated for strabismus (cover/uncover test), with a referral to ophthalmology if visual concerns are indicated.

Individuals with PWS are at a higher risk for dental caries because of decreased saliva. Regular dental visits and good dental hygiene are recommended.

An examination of the skin should be performed at all visits because of picking behavior, possible infection, and bleeding. Keeping nails short and cleaning and covering wounds can help minimize damage.

Individuals should be monitored for known complications of obesity. Blood pressure should be checked regularly, and hypertension should be treated as in the general population. Glycosylated hemoglobin and a lipid profile should be measured annually in adults with obesity. Type 2 diabetes should be treated as in the general population.

Because individuals with PWS have a high pain threshold, all complaints of pain or change in behavior or appetite should be taken seriously. Physicians should thoroughly examine individuals and have a low threshold for imaging studies or further workup.

### Transition Needs

Transition plans should begin in childhood or early adolescence to facilitate a smooth transition to adult services. Issues including vocational training, guardianship, housing, and adult medical providers should be addressed. Individuals with PWS will require a supportive environment throughout their lives.

### Prognosis

Obesity accounts for most cases of morbidity or mortality in PWS. Deaths are often the result of cardiorespiratory failure or complications of sleep apnea (cor pulmonale). There have been reports of deaths from choking because of rapid food consumption. Overeating has resulted in gastric necrosis and rupture, which presented with only mild clinical signs. Individuals with PWS have a high pain tolerance, so minor symptoms, such as abdominal pain, vomiting, or decreased appetite should prompt further workup, often including urgent imaging.

Central adrenal insufficiency (CAI) may be present in individuals with PWS. Some of the sudden deaths in individuals with PWS may be explained by the CAI in times of stress. This should be discussed with the individual's endocrinologist, and individuals may be tested for CAI.

Although PWS remains a complex condition, regular follow-up with the multidisciplinary physician-led team can lead to early intervention or prevention of common complications. Strategies to prevent obesity and the initiation of growth hormone replacement have changed the prognosis for individuals with PWS. Through early identification, diagnosis, and implementation of behavioral strategies, hyperphagia and obesity can be decreased, thereby avoiding the complications of obesity. Increased awareness allows parents and families to seek counseling and support through community groups and professionals. With continued support, quality of life can improve for individuals with PWS and their families.

## Chapter 319

# PRESEPTAL AND ORBITAL CELLULITIS

Ellen R. Wald, MD

The pediatrician often has the opportunity to manage the child for whom the chief complaint is a swollen eye. Many of these children have trivial or self-limited disorders, but others can have sight- or life-threatening problems. Noninfectious causes of the swollen eye can often be distinguished from infectious causes by a detailed history of the onset and progression of the eye swelling. Infectious causes of eye swelling are usually acute in presentation. Differentiating between preseptal (common) and orbital (rare) causes of eye swelling is critical to management and can usually be accomplished on the basis of the physical examination.

## NONINFECTIOUS CAUSES OF THE SWOLLEN EYE

The noninfectious causes of swelling of or around the eye include blunt trauma (leading to the proverbial *black eye*), tumor, local edema, and allergy. In cases of blunt trauma, history provides the key to the diagnosis. Eyelid swelling continues to increase for 48 hours and then resolves over several days. Tumors that characteristically involve the eye include hemangioma of the lid, ocular tumors such as retinoblastoma and choroidal melanoma, and orbital neoplasms such as neuroblastoma, rhabdomyosarcoma, and Langerhans cell histiocytosis. Tumors usually cause a gradual onset of proptosis in the absence of inflammation. An orbital pseudotumor, an autoimmune inflammation of the orbital tissues, exhibits eyelid swelling, red eye, pain, and decreased ocular motility. Hypoproteinemia and congestive heart failure cause eyelid swelling as a result of local edema. Characteristic findings are bilateral, boggy, nontender, nondiscolored, soft-tissue swelling. Allergic inflammation includes angioneurotic edema or contact hypersensitivity. Superficially, these problems can resemble the findings in acute infection. However, the presence of pruritus and the absence of tenderness are helpful distinguishing characteristics of allergic inflammation.

## INFECTIOUS CAUSES OF THE SWOLLEN EYE

Infections can spread to the eye from contiguous structures. Veins that drain the orbit, the ethmoid and maxillary sinuses, and the skin of the eye and

periorbital tissues (Figure 319-1) constitute an anastomosing and valveless network. This venous system provides opportunities for the spread of an infection from one anatomic site to another and predisposes the child to the involvement of the cavernous sinus, meninges, and brain.

The relationship between the eye and the paranasal sinuses is shown in Figure 319-2. The roof of the orbit is the floor of the frontal sinus, and the floor of the orbit is the roof of the maxillary sinus. The medial wall of the orbit is formed by the frontal maxillary process, the lacrimal bone, the lamina papyracea of the ethmoid bone, and a small part of the sphenoid bone. Infections originating in the mucosa of the paranasal

**Figure 319-1** The valveless venous system of the orbit and its many anastomoses.

**Figure 319-2** The relationship between the eye and the paranasal sinuses is shown schematically. The roof of the orbit, the medial wall, and the floor are shared by the frontal, ethmoid, and maxillary sinuses, respectively.

**Figure 319-3** The orbital septum is a connective tissue extension of the periosteum that is reflected into the upper and lower lid.

sinuses can spread to involve the bone (osteitis with or without subperiosteal abscess) and the intraorbital contents. Orbital infections can occur through natural bony dehiscences in the lamina papyracea of the ethmoid or frontal bones or via foramina through which the ethmoidal arteries pass.

The orbital septum is a connective-tissue extension of the periosteum (or periorbital) that is reflected into the upper and lower eyelids (Figure 319-3). The infection of tissues anterior to the orbital septum is described as a *periorbital* or *preseptal* infection (the terms may be used interchangeably; preseptal will be used throughout the rest of the chapter). The septum provides a nearly impervious barrier to the spread of an infection to the orbit. Although preseptal cellulitis, or periorbital cellulitis, is often considered to be a diagnosis, the term is an inadequate diagnostic label unless accompanied by a modifier that indicates the likely pathogenesis.

Infectious causes of preseptal cellulitis occur in the following 3 settings:

1. Secondary to a localized infection or inflammation of the conjunctiva, eyelids, or adjacent structures (eg, conjunctivitis, hordeolum, acute chalazion, dacryocystitis, dacryoadenitis, impetigo, traumatic bacterial cellulitis)
2. Secondary to hematogenous dissemination of nasopharyngeal pathogens to the periorbital tissue
3. As a manifestation of inflammatory edema in children with acute sinusitis (Box 319-1)

Infections behind the septum that cause eyelid swelling include subperiosteal abscess, orbital abscess, orbital cellulitis, cavernous sinus thrombosis, panophthalmitis, and endophthalmitis. Although all of these entities can be labeled as orbital cellulitis, a systematic approach allows a more specific diagnosis, thereby directing management. Infections intrinsic to the eye (eg, conjunctivitis, keratitis, endophthalmitis) are discussed in Chapter 188, Red Eye/Pink Eye.

### BOX 319-1 Infectious Causes of Preseptal and Orbital Cellulitis

#### PRESEPTAL CELLULITIS

- Localized infection of the eyelid or adjacent structure
- Conjunctivitis
- Hordeolum
- Dacryoadenitis
- Dacryocystitis
- Bacterial cellulitis (trauma)
- Hematogenous dissemination
- Bacteremic periorbital cellulitis
- Acute sinusitis
- Inflammatory edema

#### ORBITAL CELLULITIS (POSTSEPTAL)

- Subperiosteal abscess
- Orbital abscess
- Orbital cellulitis
- Cavernous sinus thrombosis
- Hematogenous dissemination
- Endophthalmitis
- Traumatic inoculation
- Panophthalmitis

## PRESEPTAL INFECTIONS

### Preseptal Cellulitis Infections After Trauma

Occasionally, preseptal cellulitis results from secondary bacterial infection of local skin injury (including lacerations, abrasions, and even insect bites), or with the spread of an infection from a focus of impetigo. The traumatic injury may be extremely modest or completely inapparent. Loosely bound periorbital soft tissues permit impressive swelling to accompany minor infection. The overlying skin can be bright red with subtle textural changes, or intense swelling can lead to shininess (Figure 319-4). Some children have fever, but most are afebrile despite dramatic local findings. The peripheral white blood cell count is variable. In these cases, cellulitis, similar to that on any other cutaneous area, is caused by *Staphylococcus aureus* or *Streptococcus pyogenes*. These are among the most common causes of preseptal cellulitis.

Several other causes of lid cellulitis have been reported; these are much less common but are interesting to consider. Periocular cellulitis and abscess formation have resulted from infection with *Pasteurella multocida* in a healthy child who sustained a cat bite and cat scratch to the eyelid. Ringworm (caused by *Trichophyton* species) is also recognized as a cause of lid infection (leading to preseptal cellulitis) characterized by redness, swelling, and ulceration and vesicle formation. Palpebral myiasis (larval infection) involving the eyelid of a 6-year-old child was reported from the Massachusetts Eye and Ear Infirmary. A small draining fistula through which the larvae were extracted was noted at the site of the erythematous and edematous lid. Several cases of

**Figure 319-4** A 3-year-old boy with rapid onset of left eyelid swelling and erythema after he incurred a small laceration at the lateral margin of the left eye. He had had an upper respiratory tract infection for 10 days. Group A *Streptococcus* was recovered from the wound.

cellulitis of the eyelid caused by *Bacillus anthracis* have been reported from Turkey. The diagnosis was suggested when the erythematous and swollen lid developed an eschar. Scrapings showed the presence of Gram-positive rods, which were confirmed by culture. A primary case of lymphocutaneous *Nocardia brasiliensis* of the eyelid was reported in an adult hunting in England 2 weeks before presentation following a small abrasion on his lower eyelid. In countries where *Mycobacterium tuberculosis* is endemic, this etiology should also be considered in children who present with a swollen lid. Raina and colleagues reported 7 children with tuberculous lesions of their eyelids. In most cases, the presentation was relatively indolent (2 days to 2 months), and fistulas occurred during the course of conventional antibiotic treatment for more typical bacterial disease. The diagnosis was confirmed by a positive tuberculin skin test, the identification of a primary focus of tuberculosis in lung or bone, and the response to antituberculous therapy.

Children with bacterial cellulitis of traumatized areas rarely have bacteremia. A precise bacteriologic diagnosis is made through the culture of the exudate from the wound. If there is no drainage, then a careful attempt at tissue aspiration may be undertaken if it can be done safely (ie, at a distance far enough from the orbit that no damage to the eye can occur). This procedure may be performed on inpatients or outpatients. A tuberculin syringe with a 25-gauge needle can be used for aspiration. Usually, only a minuscule amount of infected material can be aspirated. A small volume of nonbacteriostatic saline (0.2 mL) is drawn into the syringe before the procedure. The saline is not injected into the skin; instead, it is used to expel the small volume of tissue fluid onto chocolate agar for culture. The treatment of preseptal cellulitis likely caused by *S aureus* or *S pyogenes* should be undertaken aggressively because improperly treated infection may lead to cavernous sinus thrombosis. After local cultures are obtained, vancomycin should be initiated (at 15 mg/kg/dose every 6 hours) in communities where methicillin-resistant

*S aureus* (MRSA) is prevalent. If cultures disclose an etiology other than MRSA, intravenous treatment can be tailored to the isolate. Oral therapy can be used to complete a 10-day course of treatment after a substantial improvement in local findings.

### Bacteremic Periorbital Cellulitis

Bacteremia as the pathogenetic mechanism of periorbital cellulitis is very uncommon since the introduction of conjugate vaccines for *Haemophilus influenzae* type b and *Streptococcus pneumoniae* (pneumococcal conjugate vaccine 7 [PCV7] and 13 [PCV13]) in 2000 and 2010, respectively. The child with bacteremic periorbital cellulitis, which is most often seen in infants younger than 18 months, has had a viral upper respiratory infection (URI) for several days. A sudden increase in temperature occurs ( $>102.2^{\circ}\text{F}$  [ $39^{\circ}\text{C}$ ]) accompanied by the acute onset and rapid progression of eyelid swelling. Swelling usually begins in the inner canthus of the upper and lower eyelid and can obscure the eyeball within 12 hours. Periorbital tissues are markedly discolored and usually erythematous, although if the swelling has been rapidly progressive, the area may have a violaceous discoloration. The child's resistance to examination commonly leads to the erroneous impression of tenderness. Retraction or separation of the lids reveals that the globe is normally placed and extraocular eye movements are intact. If retraction of the lids is not possible, then an orbital computed tomography (CT) scan may be necessary. The young age, high fever, and rapid progression of findings differentiate bacteremic preseptal cellulitis from other causes of swelling around the eye (Figure 319-5).

A precise bacteriologic diagnosis is made by the recovery of the organism from blood culture. If tissue aspiration is performed, a culture of the specimen may have a positive result.

The bacteremia usually occurs during the course of a viral URI from a portal of entry in the nasopharynx. This process is akin to the mechanism of most infections caused by *Haemophilus influenzae* type b (Hib) and some infections caused by *S pneumoniae*.

The radiographs of the paranasal sinuses of children with bacteremic periorbital cellulitis are often abnormal. However, the abnormalities almost certainly reflect the viral respiratory syndrome that precedes and probably predisposes the child to the bacteremic event rather than a clinically significant sinusitis. Bacteremic cellulitis rarely arises from the paranasal sinus cavities, as evidenced by the finding that typeable *H influenzae* organisms were almost never recovered from maxillary sinus aspirates and, similarly, were rarely recovered from abscess material in children who had serious local complications of paranasal sinus disease, such as subperiosteal abscess. Although *S pneumoniae* can cause subperiosteal abscesses in children with acute sinusitis, these children are not usually bacteremic.

The treatment for suspected bacteremic periorbital cellulitis requires parenteral therapy. *S pneumoniae* is the most likely cause in a child who has received both the Hib and pneumococcal conjugate vaccine series. Because this infection is usually bacteremic in the age group in whom the meninges are susceptible to inoculation, using an advanced-generation cephalosporin

**Figure 319-5** A 10-month-old with bacteremic periorbital cellulitis due to *Haemophilus influenzae* type b.

**Figure 319-6** A 3-year-old child with inflammatory edema caused by ethmoiditis.

such as ceftriaxone (100 mg/kg/day, divided into 12-hour doses or given once daily) may be prudent. This regimen is appropriate for immunized and nonimmunized children. A lumbar puncture should be performed unless the clinical picture precludes meningitis. Addition of vancomycin (60 mg/kg/day divided into doses every 6 hours) is appropriate if cerebrospinal fluid pleocytosis is present. When the evidence of a local infection has resolved and no meningitis is present, oral antimicrobial therapy is prescribed to complete a 10-day course.

### Preseptal (Periorbital) Cellulitis Caused by Inflammatory Edema of Sinusitis

Several complications of paranasal sinusitis can result in swelling around the eye. The most common and least serious complication is often referred to as *inflammatory edema* or a *sympathetic effusion*. This entity is a form of preseptal cellulitis, although infection is confined to the sinuses.

Typically, a child who is at least 2 years old has had a viral URI for several days when swelling is noted. A history of intermittent early-morning periorbital swelling that resolves after a few hours is often present. On the day of presentation, the eyelid swelling does not typically resolve but progresses gradually (Figure 319-6). Surprisingly, striking degrees of erythema can also be present. Eye pain and tenderness are variable. Eyelids can be very swollen and difficult to evert, requiring the assistance of an ophthalmologist. However, no displacement of the globe or impairment

of extraocular eye movements occurs. Fever, if present, is usually low grade.

The peripheral white blood cell count is unremarkable. Blood culture results are always negative. If a tissue aspiration is performed, culture of the specimen has a negative result. Sinus radiographs show ipsilateral ethmoiditis or pansinusitis. The age of the child, gradual evolution of lid swelling, and modest temperature elevation differentiate inflammatory edema from the uncommon case of bacteremic periorbital cellulitis.

The pathogenesis of sympathetic effusion or inflammatory edema is attributable to the venous drainage of the eyelid and surrounding structures. The inferior and superior ophthalmic veins, which drain the lower lid and upper lid, respectively, pass through or just next to the ethmoid sinus. When the ethmoid sinuses are completely congested, physical impedance of venous drainage occurs, resulting in soft-tissue swelling of the eyelids, maximal at the medial aspect of the lids. In this instance, infection is confined within the paranasal sinuses. The globe is not displaced, and no impairment of the extraocular muscle movements occurs. However, inflammatory edema is part of a continuum, with more serious complications resulting from the spread of infection outside the paranasal sinuses into the orbit. Infection rarely progresses despite the initial optimal management of sympathetic effusions.

The infecting organisms in cases of inflammatory edema are the same as those that cause uncomplicated acute sinusitis (ie, *S pneumoniae*, nontypeable *H influenzae*, *Moraxella catarrhalis*). Antibiotic therapy can

**Figure 319-7** A 12-year-old boy with orbital cellulitis. He had a 5-day history of eye pain and progressive swelling of the eyelids, which were markedly erythematous. When his eyelids were retracted, anterior and lateral displacement of the globe and impairment of upward gaze were noted.

be given orally if, at the time of the first examination, the eyelid swelling is modest, the child does not look toxic, and the parents will adhere to management. Amoxicillin-clavulanate at 90 mg/kg/day in 2 divided doses is preferred to provide the most comprehensive coverage. Otherwise, admission to the hospital and parenteral treatment should be undertaken.

The only source of bacteriologic information is that obtainable by maxillary sinus aspiration, which is usually not performed. Appropriate agents for outpatient therapy have activity against  $\beta$ -lactamase-producing organisms (eg, amoxicillin-potassium clavulanate, cefuroxime axetil, cefpodoxime proxetil). Parenteral agents include ceftriaxone and ampicillin-sulbactam. The latter combination, although not approved for children younger than 12 years, is an attractive choice. Although the use of topically applied intranasal decongestants such as oxymetazoline has not been systematically evaluated, such agents may be helpful during the first 48 hours. After several days, once the affected eye has returned to near normal, an oral antimicrobial agent is substituted to complete a 10- to 14-day course of therapy.

### ORBITAL INFECTIONS

The child or adolescent with true orbital disease secondary to sinusitis usually has a sudden onset of erythema and swelling about the eye after several days of a viral URI (Figure 319-7). Eye pain can precede

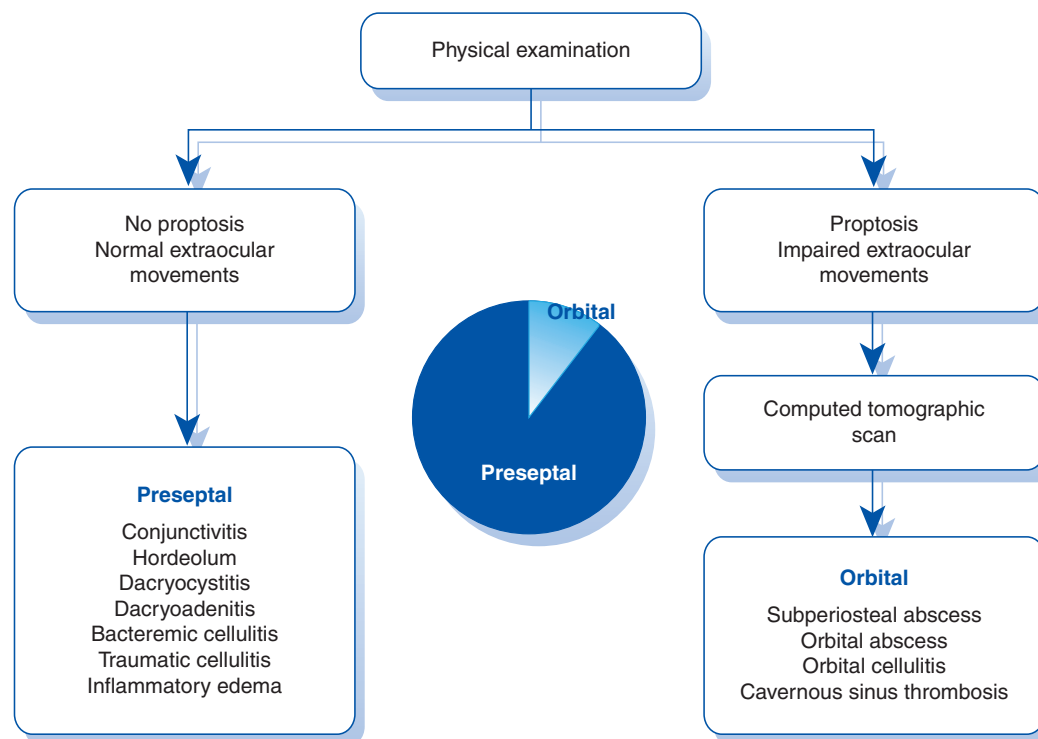

**Figure 319-8** Axial computed tomography scan shows a subperiosteal abscess extending from the right ethmoid sinus.

swelling and is often dramatic. The presence of fever, systemic signs, and toxicity is variable. Orbital infection is suggested by proptosis (with the globe displaced usually anteriorly and downward), impairment of extraocular eye movements (most often upward gaze), chemosis (edema of the bulbar conjunctiva), or, late in the evolution of the infection, loss of visual acuity or decreased pupillary reaction. Fortunately, orbital infection is the least common cause of the swollen eye.

Most orbital infections involve the formation of a subperiosteal abscess that, in young children, results from ethmoiditis and ethmoid osteitis. In the adolescent, subperiosteal abscess can be a complication of frontal sinusitis and osteitis. Orbital cellulitis rarely evolves, without formation of subperiosteal abscess, by direct spread from the ethmoid sinus to the orbit via natural bony dehiscences in the bones that form the medial wall of the orbit.

Imaging studies are usually performed if orbital disease is suspected. They help determine if subperiosteal abscess, orbital abscess, or orbital cellulitis is the cause of the clinical findings (Figure 319-8). In the presence of a large, well-defined abscess, complete ophthalmoplegia or impairment of vision prompts

**Figure 319-9** Algorithm for the differential diagnosis of the swollen eye.

the operative drainage of the paranasal sinuses and the abscess. Several studies have reported on the successful drainage of a subperiosteal abscess via endoscopy. This method, performed through an intranasal approach, has been successful, thereby avoiding an external incision. In many cases, a well-defined abscess is not seen. Instead, inflammatory tissue is observed interposed between the lateral border of the ethmoid sinus and the swollen medial rectus muscle. Usually, children with these symptoms are managed successfully with antimicrobial therapy alone as are children with small orbital abscesses. On occasion, the CT scan can be misleading, suggesting an abscess when inflammatory edema is present; accordingly, the clinical course is the ultimate guide to management.

Empirical antimicrobial therapy should be chosen to provide activity against *S aureus*, *S pyogenes*, *Streptococcus anginosus*, and anaerobic bacteria of the upper respiratory tract (anaerobic cocci, *Bacteroides* species, *Prevotella* species, *Fusobacterium* species, and *Veillonella* species) in addition to the usual pathogens associated with acute sinusitis (ie, *S pneumoniae*, *H influenzae*, and *M catarrhalis*). Appropriate selections include ceftriaxone (100 mg/kg/day given as a single daily dose) or ampicillin-sulbactam (200 mg/kg/day divided into doses every 6 hours) plus vancomycin. Immunocompromised children and diabetic children are at a higher risk of fungal orbital cellulitis (especially *Mucor* species). If surgery is performed, then a Gram stain of material drained from the sinuses or the abscess guides the consideration

of additional drugs or an altered regimen. When the final results of the culture are available, antibiotic therapy may be changed, if appropriate. Intravenous therapy is maintained until the infected eye appears nearly normal. At that time, oral antibiotic therapy can be substituted to complete a 2-week course of treatment.

## SUMMARY

The child with a swollen eye is commonly seen in primary care. Figure 319-9 depicts an approach to diagnosis depending on physical examination. By far, children with preseptal infections are most common.

## WHEN TO REFER

Refer a child with a swollen eye to an ophthalmologist in the following instances:

- When visual acuity is compromised
- When any eyelid swelling occurs in an immunocompromised child or a child with diabetes; referral should be immediate because this situation may require urgent treatment
- If conjunctivitis is the diagnosis and if the clinical findings do not begin to improve after 5 days; this circumstance suggests a diagnosis of either adenovirus or herpes simplex infection
- When a chalazion is large and causes local irritation because incision and drainage of the chalazion may be required
- When dacryoadenitis has not begun to resolve after 5 days

**WHEN TO ADMIT**

Hospitalize a child with a swollen eye in the following instances:

- Diagnosis bacteremic periorbital cellulitis, for parenteral therapy
- Diagnosis of likely bacterial cellulitis is made, for parenteral therapy when the process is extensive, the child is febrile, or the child is younger than 5 years
- Diagnosis is dacryocystitis, for parenteral therapy and consultation with an ophthalmologist
- Oral therapy failed
- Eye is swollen shut and parenteral antibiotics and close observation are required for the management of inflammatory edema (sympathetic effusion)
- Proptosis, impairment of extraocular movements, diminished pupil reaction, or loss of visual acuity occurs; these situations are the herald signs of subperiosteal abscess, orbital abscess, orbital cellulitis, and cavernous sinus thrombosis, and their presence indicates the need for parenteral antibiotics and the likely need for surgical intervention

**Chapter 320**  
**PSORIASIS**

Jennifer L. Reeve, MD, PhD; Ginette A. Hinds, MD;  
Richard J. Antaya, MD

Psoriasis is a T cell–mediated chronic inflammatory disease that is characterized clinically by well-demarcated, erythematous plaques with an overlying silvery-white scale. Psoriasis affects approximately 2% of the adult population, and 31% to 45% of affected adults noted onset during childhood. While psoriasis can occur as early as infancy, the incidence of pediatric psoriasis increases with age, with an overall annual incidence of 48/100,000 and an estimated prevalence of 0.7% to 1.5%.

Psoriasis is reportedly more common in girls than boys, with a female:male ratio approaching 2:1, although in some studies, no sex predilection was found. Childhood- and adult-onset psoriasis occur more often in the white population compared to the black, Asian, and Native-American populations.

Both genetic and environmental factors play a role in the development of psoriasis. Childhood psoriasis has been associated with a family history of psoriasis in first-degree relatives. The human leukocyte antigen (HLA) Cw6 allele is the strongest genetic link to early-onset psoriasis and guttate psoriasis. Genes involved in IL-23 (*IL-12B*, *IL-23R*, *IL-23A*), Tumor necrosis factor- $\alpha$  (*TNF- $\alpha$* ) (*TNFAIP3*, *TNIP1*) signaling pathways, and TH2 cytokines (*IL4/13*) have also been implicated through large-scale genome-wide association studies. Environmental triggers that likely precipitate or exacerbate childhood psoriasis include streptococcal infections, upper respiratory infections, trauma, and psychological stress.

**CLINICAL VARIANTS OF PSORIASIS**

Psoriasis can occur as one of several types (see summary in Table 320-1). Plaque-type psoriasis is the most common type of psoriasis in both adults and children. Plaque psoriasis usually produces large, erythematous, well-circumscribed plaques covered by the characteristic silvery-white psoriatic scale (Figure 320-1 and Figure 320-2). Presentations vary from solitary lesions to widely distributed plaques. The scalp, elbows, knees, and lumbosacral regions are the most commonly affected areas, often with bilateral symmetry (Figure 320-3, Figure 320-4, and Figure 320-5). The scalp is one of the most frequently involved sites in children and may be misdiagnosed as seborrheic

**Table 320-1** Psoriasis Variants

VARIANT OF PSORIASIS	MORPHOLOGY	DISTRIBUTION
Plaque psoriasis	Large erythematous plaques with overlying silvery-white or grayish scale	Scalp, face, elbows, knees, lumbosacral area, gluteal crease, umbilicus
Inverse psoriasis	Bright-red glazed erythema with minimal to no scale	Diaper area, axillae, groin, postauricular area
Pustular psoriasis	Widespread bright-red erythema studded with 1- to 2-mm pustules; deep-seated 2- to 4-mm pustules in areas of erythema and scaling	Widespread; especially flexural areas, genitals, finger webs, palms, and soles
Erythrodermic psoriasis	Bright-red erythema with massive exfoliation	Widespread

**Figure 320-1** Plaque psoriasis. Large, well-circumscribed plaque covered by silvery-white scale.

**Figure 320-2** Plaque psoriasis on the penis and scrotum.

dermatitis or tinea capitis (Figure 320-6). Facial psoriatic lesions, especially around the eyes, are more common in affected children and may be the only involved site.

Inverse psoriasis—psoriasis that involves intertriginous areas such as the postauricular area, axillae, groin, and the genital and perianal areas—is also common in children. Inverse psoriasis tends to produce a glazed, bright-red erythema, sometimes with fissuring, and the characteristic psoriatic scale is usually

**Figure 320-3** Thin psoriatic plaques on the knees.

**Figure 320-4** Psoriasis involving the gluteal cleft.

absent (Figure 320-7). Psoriatic diaper rash can be the initial presentation of psoriasis in children younger than 2 years and can be difficult to differentiate from other causes of diaper dermatitis.

Guttate psoriasis is more commonly seen in children and adolescents than in adults, and it can be the first manifestation of psoriasis. In guttate psoriasis, the lesions tend to be 2 to 10 mm in size, widespread, and symmetrically distributed. They are round or oval erythematous papules and plaques with a silvery-white scale, often with a predilection for the trunk and proximal extremities (Figure 320-8 and Figure 320-9). Guttate psoriasis can be triggered by

**Figure 320-5** Plaques of linear psoriasis on the shin.

**Figure 320-6** Tinea amiantacea. Scales are thick and strongly adherent, encasing the underlying hair, producing an asbestos-like appearance. This can be a feature of seborrheic or atopic dermatitis but is most commonly associated with psoriasis of the scalp.

**Figure 320-7** Diaper area psoriasis (inverse psoriasis) with bright-red, glazed erythema. Note the absence of the characteristic scale.

**Figure 320-8** Guttate psoriasis. Note the small, droplike plaques.

**Figure 320-9** Guttate psoriasis. Guttate psoriasis has a predilection for the trunk and proximal extremities.

**Figure 320-10** Pustular psoriasis. Pink plaques studded with superficial (subcorneal) pustules.

group A streptococcal infection of the oropharynx and perianal skin, but in some cases an inciting infection is never found.

Childhood pustular psoriasis is rare, but it can be the first manifestation of psoriasis in infants and children. The cause of pustular psoriasis in children is unknown, but several triggers have been implicated, including dental and upper respiratory tract infections, streptococcal infection, withdrawal of systemic corticosteroids, and vaccinations. In addition, experts have postulated that a relationship exists between a history of severe seborrheic dermatitis and the development of pustular psoriasis. Pustular psoriasis can be limited to the palms and soles (palmoplantar pustular psoriasis), but it more commonly occurs as an explosive generalized eruption of pustules on psoriatic plaques or on previously normal skin (generalized pustular psoriasis). These patients develop extensive areas of bright erythema studded with sterile pustules (Figure 320-10), sometimes associated with fever and malaise. The pustules coalesce into lakes, followed by extensive desquamation. Mucous membrane and nail involvement occasionally occurs. Palmoplantar pustular psoriasis and generalized pustular psoriasis tend to follow a chronic, cyclic course, with unexplained exacerbations and remissions, but are generally benign.

Erythrodermic psoriasis is rare in children. It is characterized by diffuse erythema, exfoliation, and decreased ability to regulate body temperature. This type of psoriasis can be complicated by electrolyte imbalances, cardiovascular compromise, and sepsis, and it is considered a dermatologic emergency.

**Figure 320-11** Nail psoriasis. Mild involvement with discoloration, onycholysis, and pitting.

Many children with psoriasis have nail involvement (Figure 320-11). Nail pitting, the most characteristic finding, is best described as multiple, small, irregularly spaced depressions in the nail plate. Other nail findings in psoriasis include discoloration, onycholysis (distal separation of the nail from the nail bed), longitudinal striations, and subungual hyperkeratosis. Evaluation for characteristic nail changes can help in the diagnosis of psoriasis when it is otherwise not apparent.

## COMORBIDITIES

Juvenile psoriatic arthritis (JPsA) is uncommon in children. It can occur with either plaque or guttate psoriasis, and in 80% of individuals, skin lesions precede the onset of psoriatic arthritis. The clinical presentation of JPsA is similar to that seen in juvenile idiopathic arthritis (JIA), and JPsA is thought to be a subset of JIA with specific criteria defined by the International League of Associations for Rheumatology. Individuals must have both arthritis and psoriasis or arthritis with at least 2 associated features (nail pitting or onycholysis, dactylitis, family history of psoriasis in a first-degree relative), and other subsets (eg, systemic JIA, rheumatoid factor–positive disease, enthesitis-related arthritis) must be excluded. Like JIA, JPsA most commonly presents with oligoarticular disease affecting the knees and ankles; however, involvement of the wrists and small joints of the hands (distal interphalangeals) and feet, along with the presence of a bluish discoloration over affected joints, may help distinguish between these entities. Early-onset JPsA (ages 2–3 years) is more often seen in females and is associated with anterior uveitis and antinuclear antibodies positivity, while late-onset JPsA (ages 10–12 years), may present with enthesitis and axial disease and is linked to patients with HLA-B27 haplotype.

An association between cardiovascular disease and psoriasis has been established in adults. Recent evidence also indicates that children with psoriasis have a higher rate of obesity, dyslipidemia, hypertension, and diabetes mellitus compared to their peers. Further studies are needed to determine whether this is a result of chronic systemic inflammation or whether

it is caused by associated risk factors; however, it is important to consider monitoring for metabolic disease in these high-risk children.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for plaque psoriasis includes other papulosquamous disorders such as atopic dermatitis (AD) and pityriasis rubra pilaris (PRP). Compared to the lesions of AD, psoriatic plaques tend to be more clearly demarcated from the surrounding uninvolved skin and are usually less pruritic than AD lesions. In addition, AD lesions lack the characteristic silvery-white scale of psoriasis. Psoriasis generally tends to localize to the extensors, whereas AD preferentially affects flexural areas. However, some children do exhibit a psoriasis-AD overlap.

Juvenile PRP can be the most difficult condition to differentiate from psoriasis. However, in addition to biopsy findings, the classic salmon color of PRP lesions, the focal areas of sparing, and follicular accentuation help clinically distinguish this condition from psoriasis.

Pustular psoriasis may be confused with infectious pustular eruptions, such as disseminated candidiasis or staphylococcal scalded skin syndrome. A skin biopsy, Gram stain, and culture of the contents of several pustules can help differentiate these conditions from pustular psoriasis. Noninfectious pustular eruptions, such as pustular drug eruptions, may also mimic pustular psoriasis. The history of a recently started medication and a skin biopsy can sometimes help differentiate between pustular psoriasis and a pustular drug eruption. While the histopathological distinction between these entities is often challenging, the presence of eosinophils and necrotic keratinocytes suggests a pustular drug eruption, while tortuous blood vessels and psoriasiform epidermal hyperplasia point to the diagnosis of pustular psoriasis.

The differential diagnosis of psoriatic diaper rash and other forms of inverse psoriasis includes seborrheic dermatitis, Langerhans cell histiocytosis, candidal intertrigo, and contact dermatitis.

Scalp psoriasis may be mistaken for tinea capitis or seborrheic dermatitis. Performing a potassium-hydroxide preparation and a fungal culture of the scale is important to rule out tinea capitis, because the treatment for scalp psoriasis (topical corticosteroids) can exacerbate tinea capitis. In contrast to seborrhea, scalp psoriasis is more likely to present with discrete, well-defined, thicker white scaly plaques, lack greasy scale, and extend onto the forehead, posterior neck, and retroauricular areas.

In guttate psoriasis, the differential diagnosis includes pityriasis rosea, tinea corporis, pityriasis lichenoides, and secondary syphilis.

The nail changes seen in psoriasis can also be seen in other conditions. For example, nail pitting can also be seen in alopecia areata, and nail discoloration, onycholysis, and subungual hyperkeratosis are also features of onychomycosis.

Box 320-1 lists issues to address when evaluating a child suspected of having psoriasis. Laboratory tests important in diagnosing psoriasis are summarized in Table 320-2.

BOX 320-1 Issues to Address When Evaluating a Child Suspected of Having Psoriasis

- Family history of psoriasis
- Recent history of streptococcal throat or perianal infection
- Current medications
- Frequency and duration of eruptions
- Tendency for lesions to appear on traumatized skin (eg, sunburned, scratched, tattooed) (Koebner phenomenon)
- Nail changes (eg, nail pitting)
- Behavior of lesions in response to UV light
- Joint pains
- Previous treatment modalities and their efficacy

UV, ultraviolet.

Table 320-2 Laboratory Testing in Diagnosing Psoriasis

LABORATORY TEST	REASON
Bacterial culture of oropharynx and perianal area; antistreptolysin titer	Rule out streptococcal infection, especially in guttate psoriasis; may play a role in pustular psoriasis
Potassium hydroxide preparation of scale	Rule out fungal infection, especially in scalp psoriasis and annular lesions
Skin biopsy	Confirm clinical diagnosis of psoriasis, especially in atypical presentations

MANAGEMENT

One of the most important considerations in the management of psoriasis in children is the psychosocial impact of the disease on the affected child and the child’s family. Psoriasis can adversely effect the quality of life in children, and its effect is comparable to that of other chronic childhood diseases. Furthermore, a psychological disease is diagnosed and treated more often in pediatric patients with psoriasis compared to psoriasis-free controls. Thus, emphasis must be placed on educating the child, siblings, and parents, as well as teachers and classmates, about the nature of psoriasis. Affected families should be provided with information about available psoriasis support groups. In addition, psychological counseling should be sought to equip these children with effective coping skills for this chronic and potentially disfiguring disease.

Another important consideration in the management of psoriasis is the identification and elimination of potential triggers. Streptococcal infection, medications (eg, lithium, beta blockers, interferon, TNF-alpha inhibitors, systemic corticosteroids), stress, and skin

trauma are known triggering or exacerbating factors in psoriasis. Children and their parents must be educated about the so-called Koebner phenomenon, or the development of psoriasis lesions in areas of trauma to the skin such as lacerations, surgical incisions, piercings, tattoos, or sunburns.

### Topical Therapy

The topical agents most commonly used to treat psoriasis in children include topical corticosteroids, calcipotriol, tar preparations, and anthralin. Less commonly used topical therapies include keratolytic agents such as salicylic acid, topical retinoids, and topical calcineurin

inhibitors. Bland emollients, such as petrolatum, are an essential part of the skin care regimen in affected children. Moisturization and application of emollients lessens the dryness and scaling associated with psoriasis and, in some cases, emollients alone may be sufficient to improve mild psoriasis. However, in most children, emollients should be used as adjunctive therapy to anti-inflammatory topical medications. Table 320-3 summarizes treatment for children with psoriasis.

### Topical Corticosteroids

Medium- to high-potency (classes II–IV) corticosteroid ointments are effective as monotherapy in many cases

**Table 320-3** Treatment of Psoriasis in Children

AGENT	USE	SIDE EFFECTS AND COMMENTS	EXAMPLES
<b>TOPICAL AGENTS</b>			
Emollients	Decrease dryness and scaling; useful in mild psoriasis; use as adjunctive therapy in more severe disease	<ul style="list-style-type: none"> <li>No side effects</li> <li>Should not replace medicated topicals in children with significant disease</li> </ul>	<ul style="list-style-type: none"> <li>Petroleum jelly</li> <li>Aquaphor ointment</li> <li>Theraplex emollient</li> </ul>
Topical corticosteroids	First-line therapy for all types of psoriasis; apply twice daily for 1–2 weeks, then 2–3 days per week (eg, weekends) for maintenance	<ul style="list-style-type: none"> <li>Possible cutaneous side effects: atrophy, striae, telangiectasia</li> <li>Possible systemic side effects: hypothalamic-pituitary-adrenal axis suppression, growth impairment, cataracts, glaucoma</li> <li>Avoid use of high-potency preparations on face and intertriginous areas</li> <li>Ointment is the preferred vehicle when treating psoriasis because of occlusive effect and increased potency; useful for dry, scaly lesions</li> <li>Gels readily absorbed; useful in hairy areas, but can cause dryness and irritation</li> <li>Creams rub in well and are aesthetically pleasing; may be less potent than ointment form of same drug</li> <li>Foams, solutions, and oils can be used on the scalp</li> </ul>	<ul style="list-style-type: none"> <li>Class 1 (ultrapotent) <ul style="list-style-type: none"> <li>Clobetasol propionate 0.05%</li> <li>Betamethasone dipropionate 0.05%</li> </ul> </li> <li>Class 2 and 3 (medium to high potency) <ul style="list-style-type: none"> <li>Fluocinonide 0.05%</li> <li>Betamethasone valerate 0.1%</li> <li>Triamcinolone ointment 0.1%</li> </ul> </li> <li>Class 4/5 (medium potency) <ul style="list-style-type: none"> <li>Hydrocortisone valerate 0.2%</li> <li>Mometasone 0.1% cream</li> </ul> </li> <li>Class 6/7 (low potency) <ul style="list-style-type: none"> <li>Hydrocortisone (all concentrations)</li> <li>Desonide 0.05% cream, gel and foam</li> </ul> </li> </ul>
Calcipotriol or calcipotriene	Useful alone in limited disease; useful adjunct to corticosteroids; apply once to twice daily	Irritation	<ul style="list-style-type: none"> <li>Dovonex cream or solution</li> <li>Vectical ointment</li> <li>Calcitrene ointment</li> </ul>
Coal tar preparations	Useful for thicker plaques; apply once to twice daily	<ul style="list-style-type: none"> <li>Irritation, staining, unpleasant odor, folliculitis</li> <li>Increased risk of irritation on face and intertriginous areas</li> </ul>	<ul style="list-style-type: none"> <li>LCD in combination with emollients or corticosteroids</li> <li>Liquid form in bath</li> </ul>
Anthralin	Short-contact therapy; large, thick plaques; apply for 10 minutes, then increase duration as tolerated once daily	Irritation, staining	Dithrocream 1%

**Table 320-3** Treatment of Psoriasis in Children—cont'd

AGENT	USE	SIDE EFFECTS AND COMMENTS	EXAMPLES
Topical calcineurin inhibitors	Useful for lesions on the face, genitals and intertriginous areas; apply twice daily as needed	<ul style="list-style-type: none"> <li>Occasional burning or itching with first few applications</li> <li>FDA black-box warning (theoretical malignancy risk based on oral forms)</li> </ul>	<ul style="list-style-type: none"> <li>Protopic (tacrolimus) ointment 0.03% or 0.1%</li> <li>Elidel (pimecrolimus) cream 1%</li> </ul>
Topical retinoids (tazarotene)	Useful in limited, mild to moderate disease; apply once daily (every night at bedtime)	<ul style="list-style-type: none"> <li>Dryness, local irritation</li> <li>Pregnancy category X (tazarotene)</li> </ul>	Tazorac cream or gel 0.05% or 0.1%
<b>PHOTOTHERAPY</b>			
Psoralens plus UVA	Rarely used in children	Cataracts, skin aging, skin cancer, expensive, inconvenient	Methoxsalen
UVB	Widespread psoriasis	Expensive, inconvenient, skin aging; difficult for younger children	<ul style="list-style-type: none"> <li>Broadband UVB</li> <li>Narrow band UVB (preferred)</li> </ul>
<b>SYSTEMIC AGENTS</b>			
Methotrexate	Recalcitrant widespread psoriasis; erythrodermic psoriasis, pustular psoriasis, psoriatic arthritis	Bone marrow toxicity, nausea, vomiting, fatigue, oral ulcers, hepatotoxicity	—
Cyclosporine	Recalcitrant widespread psoriasis; erythrodermic psoriasis, pustular psoriasis	Renal toxicity, hepatic toxicity, hypertension, hypertrichosis, gingival hyperplasia, immunosuppression	Neoral
Oral retinoids	Erythrodermic psoriasis, pustular psoriasis	<ul style="list-style-type: none"> <li>Cheilitis, xerosis, skin fragility, hypertriglyceridemia, skeletal abnormalities</li> <li>Avoid in adolescent girls (teratogenicity)</li> <li>Injection site reactions</li> <li>Immunosuppression and potential risk of malignancy</li> <li>Live vaccination should be avoided; caution in children with congestive heart failure (anti-TNF-<math>\alpha</math>), multiple sclerosis (anti-TNF-<math>\alpha</math>), tuberculosis risk factors</li> </ul>	Acitretin
Biologic agents (anti-TNF- $\alpha$ and anti-IL-12/23)	Severe generalized, recalcitrant psoriasis in older children; psoriatic arthritis		Etanercept, adalimumab, infliximab, ustekinumab

FDA, Food and Drug Administration; LCD, liquor carbonis detergens; TNF, tumor necrosis factor; UVA, ultraviolet A.

of childhood psoriasis. Ultrapotent (class I) corticosteroid ointments are reserved for unresponsive, thick psoriatic plaques and may be used with occlusion if necessary (eg, plastic wrap placed over topical corticosteroid on an extremity). Continuous twice-daily treatment should not last for more than 2 weeks; after 2 weeks, intermittent application (2–3 days per week) may be used for maintenance therapy. Long-term use of topical corticosteroids can lead to side effects such as striae, atrophy, telangiectasia, tachyphylaxis, and acne. When used over a large body surface area, topical corticosteroids may rarely cause pituitary-adrenal axis suppression and other systemic side effects.

Hydrocortisone 2.5% can be used for facial psoriasis, but this may be ineffective in many children. For lesions on the trunk and extremities, medium- to high-potency corticosteroids tend to be more effective. The continuous use of corticosteroids in the groin or other intertriginous areas should be avoided.

For lesions on the scalp, liquid or foam corticosteroid preparations (eg, clobetasol foam, clobetasol solution, fluocinonide solution) work well, as do corticosteroid, tar, zinc, or salicylic acid shampoos. However, parents should be warned that these products might cause dryness of the hair and scalp. The alcohol base in foam and gel preparations may also cause stinging, especially on excoriated or otherwise irritated lesions.

The nighttime application of oils, such as fluocinolone, or nonsteroid oils, such as olive, mineral, or soybean oil, can be a useful adjunct in treating scalp psoriasis in older children. These preparations can be applied to the scalp at night to loosen adherent scale and then shampooed out in the morning. The addition of low concentrations of salicylic acid (5%–6%) with or without tar (5% liquor carbonis detergens) can be effective in decreasing scale when used for 1 to 2 weeks prior to starting a topical steroid regimen. Some black

patients prefer oilier scalp preparations, such as lotions, ointments, or oils, rather than the foams or gels because the former preparations also lubricate the hair, preventing brittleness and breakage.

### **Calcipotriol (Calcipotriene)**

Calcipotriol is a vitamin-D analog that is safe and effective in treating psoriasis in children. It can be used twice a day as monotherapy in limited disease or as an adjunct to topical corticosteroids in more severe disease. The ointment form is suitable for use on any affected area, but it is more likely to cause burning and irritation on the face or groin. Calcipotriol is also available in a cream and a liquid form for use on the scalp. Calcium homeostasis is not affected by topical calcipotriene in otherwise healthy adults, with the recommended dose of 100 g ointment/week (or approximate equivalent of <50 g ointment/m<sup>2</sup>/week in children). A topical combination preparation of calcipotriene 0.005% and betamethasone dipropionate 0.064% (ointment and suspension) was approved by the US Food and Drug Administration (FDA) for children (12–17 years) for treating psoriasis (maximum 60 g suspension per week).

### **Tar Preparations**

Tar preparations can be used in an emollient base (eg, liquor carbonis detergens 5% in petrolatum) or in combination with topical corticosteroids. However, the undesirable odor and potential for staining make it difficult for children and adolescents to accept.

### **Anthralin**

Short-contact anthralin therapy can be a useful adjunct in treating thick, stubborn plaques. In short-contact therapy, anthralin 1% is applied for 10 minutes, with increasing contact time with subsequent treatments as tolerated. Side effects include local irritation and brownish staining of the skin, bathtubs, and sinks.

### **Topical Calcineurin Inhibitors**

Topical calcineurin inhibitors (tacrolimus and pimecrolimus) are preferred to topical corticosteroids for both facial and intertriginous psoriasis in children. Because the substance does not penetrate thicker plaques well, it is not particularly efficacious in other body sites. The most common adverse effect is burning with initial application, but the topical calcineurin inhibitors are generally well tolerated. Parents must be informed of the FDA black-box warning about a theoretical risk of skin cancer and lymphoma that is associated with oral forms of this medication class. These concerns are being evaluated, and currently there is no statistically significant increase in either adverse event.

### **Topical Retinoids**

The topical retinoid tazarotene can be useful in treating limited (<20% body surface area), mild to moderate psoriasis. It is FDA approved in adults with psoriasis and children with acne (>12 years of age). The most common side effect is local irritation. Tazarotene is a potential teratogen and should be used with caution in adolescent girls.

### **Phototherapy**

In older children, ultraviolet (UV) B (UVB) phototherapy may be used in conjunction with topical or systemic therapy; however, it has been shown to be well tolerated and efficacious in treating psoriasis in children as young as 3 months. The most significant short-term adverse effect associated with UVB is temporary erythema and pruritus. Narrow-band UVB (311–313 nm) can clear plaques with lower amounts of UV light and will typically achieve clearance or near complete clearance over the course of approximately 25 treatments when administered 3 times weekly. The long-term safety of UVB phototherapy in children is still unknown; however, in contrast to psoralen-UVA, the risk of skin cancer from UVB appears to be negligible. As a rule, oral psoralen plus UVA should not be administered in preadolescent children.

Goeckerman therapy is a combination of daily full body crude tar application and daily UVB treatments for 2 to 3 weeks. While this treatment is safe and effective, leading to mean remission of longer than 2 years, there are very few inpatient dermatology centers or day-hospitals in the United States that offer this option.

Excimer (308-nm) laser can be used to deliver high-dose UVB to localized plaques while sparing surrounding normal skin. There is little data regarding its use in children but it is well tolerated and efficacious in adults, requiring fewer treatments than full body UVB, and may be an option for focal disease.

### **Systemic Therapy**

Systemic treatment is indicated for severe forms of psoriasis, such as extensive plaque psoriasis, generalized pustular psoriasis, erythrodermic psoriasis, and psoriatic arthritis. However, because these forms of psoriasis are uncommon in children, clinical experience is limited in the use of systemic agents in treating childhood psoriasis. Methotrexate, oral retinoids, cyclosporine, and biologic agents have all been used in children with varying degrees of success.

### **Methotrexate**

Although methotrexate is extensively used in treating psoriasis in adults and JIA in children, its use in children with pediatric psoriasis is less common, though its efficacy and safety in this population have been demonstrated in short-term use. The side effects of methotrexate include nausea, vomiting, fatigue, oral ulcers, bone marrow toxicity, and hepatic fibrosis, and its use necessitates monitoring the child's complete blood count and liver function tests.

According to the most current guidelines, a liver biopsy after prolonged use is typically unnecessary in low risk children without lab abnormalities; furthermore, in the pediatric population, where alcohol intake and hepatitis are uncommon, clinically significant hepatotoxicity is rare. Methotrexate is administered orally or subcutaneously once weekly (0.3–0.5 mg/kg/week), typically on the weekend to avoid nausea and fatigue during school hours. The use of folic acid to reduce adverse effects, primarily gastrointestinal upset and oral ulcers, is controversial, but folic acid may be given (1 mg/day) without reducing methotrexate efficacy.

### Systemic Retinoids

Systemic retinoids (eg, acitretin, isotretinoin) have been studied in children with keratinization disorders but have not been studied in childhood psoriasis. Children with generalized pustular psoriasis have been treated successfully with acitretin. The most frequently encountered side effects are pruritus, cheilitis, and skin fragility. Chronic use of systemic retinoids has been associated with ossification of interosseous ligaments and tendons, skeletal hyperostosis, and premature epiphyseal closure, leading to concerns that retinoids might affect growth in children.

### Cyclosporine

Cyclosporine is FDA approved for treating severe plaque psoriasis in adults. It is not commonly used in children, primarily because of its immunosuppressive effects and inconsistent efficacy. The adverse effects associated with cyclosporine include hypertension, hypertrichosis, gingival hyperplasia, hyperlipidemia, and nephropathy. Cyclosporine use should be restricted to less than 1 year to limit toxicities.

### Biologic Agents

To date, 4 biologic therapies have been approved for the treatment of moderate to severe plaque psoriasis in adults, including TNF- $\alpha$  inhibitors etanercept (0.8 mg/kg subcutaneous injection weekly), adalimumab (20–40 mg subcutaneous injection every 2 weeks), and infliximab (5 mg/kg intravenously every 8 weeks), along with the IL-12/23 inhibitor ustekinumab (45 mg subcutaneous injection every 12 weeks in adults). While etanercept is approved for treating recalcitrant psoriasis in children younger than 6 years in Europe, it is currently approved only for treating JIA in children older than 2 years in the United States. Etanercept is the only TNF- $\alpha$  modulator that has been studied in a large, randomized, double-blind, phase III trial in children with moderate to severe plaque psoriasis and has demonstrated efficacy in children with few adverse events. The FDA approved adalimumab for the treatment of JIA for children older than 4 years and infliximab for Crohn disease and ulcerative colitis in children older than 6 years; each of these has been successfully used in case reports of children with recalcitrant psoriasis. There is a single case report demonstrating successful use of ustekinumab in an adolescent with psoriasis; further trials are underway in Europe.

Interestingly, anti-TNF- $\alpha$  therapy can induce new-onset psoriasis in children being treated with these drugs for other indications, such as inflammatory arthritis (rheumatoid arthritis/JIA) or inflammatory bowel disease. This paradoxical phenomenon has been demonstrated in children and presents with notable scalp involvement and palmoplantar pustulosis. It is unclear if this is a class effect or if patients can be treated with alternate anti-TNF- $\alpha$  therapies. Prior to initiating biologic therapy, patients should be screened for latent tuberculosis, human immunodeficiency virus (if at risk), and hepatitis. Complete blood count and hepatic function should also be evaluated at baseline and during treatment. In addition to immunosuppression, adverse effects of anti-TNF- $\alpha$  therapy include malignancy, demyelinating disease, and worsening of congestive heart

failure. A thorough discussion of the treatment risks and benefits is required when considering biologic therapy in children.

## Chapter 321 PYLORIC STENOSIS

Sushma Reddy, MD; Deepak M. Kamat, MD, PhD

Pyloric stenosis (PS) is among of the most common conditions requiring surgery in infancy. It is characterized by abnormal thickening of the antropyloric muscles. The intervening lumen of the pyloric channel is obstructed, causing progressive vomiting that, in turn, results in dehydration. Management of PS consists of hydration and pyloromyotomy.

### EPIDEMIOLOGICAL FEATURES

PS was recognized as a clinical entity by Hezekiah Beardsley and Harald Hirschsprung in 1887. The incidence of PS ranges from 1 to 3 per 1,000 live births. Early population-based studies reported a rise in the incidence of PS, but more recent reports indicate that the incidence seems to have leveled. Boys are affected 4 times as often as girls. However, the commonly held belief that PS primarily afflicts first-born male infants has not been confirmed. The incidence in white infants exceeds that in black, Native-American, and Asian infants. It is still unclear whether PS is an acquired or congenital entity. The onset of clinical symptoms

between 2 and 8 weeks of life is consistent with an acquired condition, whereas male predilection, familial cases, PS among twins, and an increased frequency of coexisting malformations support a genetic basis for the disease. PS is thought to be associated with the variable transmission of an inheritable trait. Transmission of the PS trait is more often from the mother compared with the father. PS develops in 5% of boys and 2.5% of girls whose fathers had PS and in 19% of boys and 7% of girls whose mothers were affected. Siblings of affected children carry a 30 times greater risk than the general population. Concordance is 0.25 to 0.44 in monozygotic twins and 0.05 to 0.1 in dizygotic twins.

## ETIOLOGY

The mechanism for hypertrophied pyloric muscle and gastric outlet obstruction is not known. It has been speculated that uncoordinated gastric peristalsis and pyloric relaxation may lead to gastric contractions against a closed pylorus, resulting in work hypertrophy of the pyloric muscle. Alterations in gastrin production, changes in breastfeeding practices, and variations in infant milk formulas are among other theories that have been proposed to explain hypertrophy of the pyloric muscle. Impaired neuronal function has been implicated in the development of PS caused by reduction in smooth-muscle vasoactive amines, neurons and nerve fibers, and interstitial *pacemaker* cells of Cajal. Investigators have proposed that deficiency of nitric oxide, a ubiquitous mediator of smooth-muscle relaxation, may be associated with the development of PS, because nitric oxide synthase is selectively depleted in the pyloric muscle of patients with PS. Studies of neuronal nitric oxide synthase gene polymorphisms suggest that this gene represents a susceptibility locus for PS.

Children with prenatal exposure to macrolides or postnatal exposure to systemic erythromycin, particularly within the first 2 weeks of life, have been observed to be at increased risk for developing PS. Postnatal prostaglandins have also been implicated in a case report.

## DIAGNOSIS

### History

Projectile, nonbilious vomiting in a full-term male infant between 3 and 6 weeks of age is a typical history associated with PS. Although the common age of symptom manifestation is 3 to 6 weeks, PS has been reported in newborns and older infants. Initially, an infant vomits a small amount of food immediately after feeding and continues to gain weight. After a few weeks, the vomiting becomes more frequent and projectile and eventually occurs after every feeding. The infant continues to be hungry immediately after vomiting. Infants with PS are usually active and alert, with lethargy ensuing only after significant dehydration. The vomitus is usually nonbilious, but may become coffee-ground with the development of gastritis and bleeding.

### Physical Examination

Physical examination reveals weight loss and dehydration. The enlarged pylorus may be felt as a firm, mobile, ovoid-shaped mass—the so-called olive. If the

infant is relaxed, then the mass can be felt in approximately 80% to 90% of cases. For this examination, the infant's feet should be elevated and the knees placed in the flexed position to relax the abdominal muscles. Two or 3 fingertips are placed in the right upper quadrant, gently advanced into the deeper tissues below the liver edge, and then slowly swept toward the umbilicus. The mass can be felt to roll under the fingertips during this sweeping motion and is usually felt to deep abdominal palpation in a quiet, cooperative infant and is almost never palpable in an agitated, crying infant with a contracted abdominal wall. The mass can be best felt immediately after an episode of projectile emesis, because at this time the pylorus is fully contracted and is at its firmest consistency. If the mass is not felt with the infant in the supine position, then palpation while the infant is lying prone may be successful. A large volume of fluid aspirated from the stomach of a fasting infant who has a history of projectile vomiting strengthens the possibility of PS. Gastric contractions, which move across the upper abdomen from left to right, may be seen in some infants. These contractions are best observed with a bright light directed across the abdomen from the infant's side, with the examiner standing at the foot of the examining table.

Although most infants with PS are otherwise healthy and genetically normal, PS has been reported with a greater frequency in infants with hiatal and inguinal hernias. Associations with malrotation, junctional epidermolysis bullosa, Hirschsprung disease, ovarian cysts, ichthyosis, Smith-Lemli-Opitz syndrome, and deletions of the long arm of chromosome 11 have also been reported.

### Laboratory Studies

Persistent vomiting caused by gastric outlet obstruction results in the continuous loss of gastric hydrochloric acid. Dehydration causes an increase in aldosterone production, leading to increased renal excretion of potassium. Loss of hydrochloric acid and potassium results in a hypochloremic, hypokalemic metabolic alkalosis. The depletion of chloride in the blood leads to an exchange of hydrogen and potassium for sodium in the distal tubule, resulting in a paradoxical aciduria. However, a spectrum of electrolyte abnormalities may also be seen. Hypoglycemia may be present and may cause seizures. Unconjugated hyperbilirubinemia is common and correlates with a decrease in hepatic glucuronosyl transferase activity, which resolves after treatment.

### Imaging Studies

With a sensitivity approaching 100%, an ultrasound scan is the most useful modality to confirm the diagnosis when PS is suspected clinically, but the hypertrophied pylorus cannot be palpated. Measurement of pyloric wall thickness, diameter, and pyloric channel length accurately establishes the diagnosis of PS. A pyloric muscle wall thickness of 3.7 mm or greater and a channel length of 17 mm or greater have been shown to have a more than 90% positive predictive value (Figure 321-1). Diagnostic criteria for wall thickness may be reduced to 3 mm in infants younger than

**Figure 321-1** Ultrasound of the abdomen shows abnormal thickening (4.5 mm) of the pyloric wall in a patient with pyloric stenosis.

30 days. An upper gastrointestinal (GI) tract contrast study may be performed in infants in whom the ultrasound is not diagnostic. Characteristic upper GI tract findings in infants with PS include an elongated and narrowed pyloric channel (string sign) with the shoulders of the hypertrophied pylorus bulging into the intestinal lumen (Figure 321-2). The palpation of a mass on physical examination alone should aid in making an accurate diagnosis in most patients. However, increasing reliance is now placed on noninvasive, highly accurate, and relatively inexpensive radiologic tests, such as the ultrasound.

### DIFFERENTIAL DIAGNOSIS

Other causes of gastric outlet obstruction, such as foregut stenosis, gastric duplications, antral webs, pylorospasm, annular pancreas, and malrotation should be considered in the differential diagnosis of an infant with nonbilious emesis. Many of these causes can be excluded by ultrasound and upper GI tract series. When a diagnosis of PS cannot be established in an infant with persistent emesis and normal ultrasound examination and upper GI tract series, the possibilities of a poor feeding regimen, gastroesophageal reflux, sepsis, intracranial disease, renal disorder, or adrenal insufficiency should be considered. Prompt diagnosis and immediate therapy are crucial in an infant with salt-losing congenital adrenal hyperplasia. This condition should be suspected in an infant with abnormal genitalia, hyponatremia, and hyperkalemia. When the workup is inconclusive, reevaluating the infant in a week to 10 days, when the pyloric mass may become palpable or the ultrasound examination or upper GI tract series may become diagnostic, is reasonable.

**Figure 321-2** Upper gastrointestinal study demonstrates a narrowed and elongated pyloric channel with a double-track appearance consistent with pyloric stenosis.

## MANAGEMENT

### Preoperative Management

In the past, infants often had overwhelming malnutrition and electrolyte abnormalities. In the current era of early diagnosis, infants rarely progress to this severe state. The anatomic correction of PS is not a surgical emergency because, although PS is a form of intestinal obstruction, gangrene and intestinal perforation do not occur with this condition. The fluid and electrolyte deficits should be corrected prior to surgical intervention.

Fluid replacement should include deficit correction, daily maintenance fluids, and replacement of ongoing losses. Replacement therapy includes continuous maintenance infusion of 5% dextrose in 0.45 normal saline with the addition of 20 mEq/L potassium chloride once urine output is established in addition to correction of other electrolyte abnormalities. Nasogastric decompression should be performed prior to the induction of anesthesia and surgery.

### Surgical Management

Once the volume and electrolyte status are corrected, the infant is ready for surgery. Ramstedt pyloromyotomy through a right upper quadrant transverse incision has been the traditional treatment for hypertrophic PS. Laparoscopic and circumumbilical approaches have now been introduced as alternative methods to open pyloromyotomy. Meta-analysis data from prospective, randomized controlled trials indicate a benefit of the laparoscopic approach, with lower rates of wound-related complications, decreased time to full feeding, and reduced postoperative length of stay.

### Medical Management

Because surgical myotomy is a reliable and safe procedure, medical therapy alone has been largely discarded during the last several decades. However, medical therapy may be considered an alternative to pyloromyotomy, particularly in children with major concurrent primary disease. Medical therapy with the anticholinergic agent atropine sulfate has been used with success, although the duration of hospital stay was prolonged. Studies comparing predominantly oral atropine sulfate to surgical myotomy have reported similar success rates.

### Postoperative Management

Postoperative vomiting occurs in most infants and will usually subside by the second to fifth feeding. Parental education regarding postoperative vomiting is important before surgery. Infants should be fed full-strength formula or human milk every 3 to 4 hours, starting 6 hours after surgery. In case of emesis, infants can be refed the amount vomited 1 hour later with resumption of the feeding schedule thereafter. This early refeeding has resulted in a reduction in the postoperative hospital stay.

### Discharge Criteria

Infants are usually discharged 24 to 48 hours after surgery. Feeding tolerance must be reassessed before discharge.

## COMPLICATIONS

### Intraoperative and Early Postoperative Complications

Morbidity and mortality from surgical repair have decreased from 50% to less than 1% in the current era. The risk of complications, such as intestinal perforation, hemorrhage, wound dehiscence, and postoperative infection, is negligible.

### Hypoglycemia

Reactive hypoglycemia has been reported in infants who have a wide variety of medical and surgical conditions and may cause respiratory arrest and death. A constant infusion of dextrose results in hyperinsulinemia and can result in severe hypoglycemia if the infusion is suddenly terminated before adequate oral feeding is established. This reaction is particularly likely if liver glycogen stores have been depleted, as has been shown in infants with PS.

### Death

The mortality rate in infants with PS is less than 0.1%. Improvement in anesthetic techniques and monitoring has contributed to these improved results. Delayed diagnosis, inadequate preoperative rehydration, pulmonary aspiration, unrecognized perforation, hypoglycemia, persistent obstruction, hemorrhage, and the presence of other associated congenital anomalies are potential causes of death.

### Late Complications

#### Postoperative Obstruction

Radiographic evaluation is necessary if vomiting persists beyond 5 to 7 days. Excessive vomiting may be

caused by persistent stenosis, gastroesophageal reflux, gastric outlet obstruction, or small-bowel obstruction attributable to adhesions. An upper GI tract contrast series may be helpful, but is also difficult to interpret. Narrowing and elongation of the pyloric channel usually persist for weeks to months after a successful operation, even in infants who have minimal or no postoperative vomiting. Subsequent operation may be indicated in the rare event of persistent pyloric obstruction.

### Long-term Outcome

The long-term outcome for patients treated for PS is excellent. Rapid gastric emptying and duodenogastric reflux have been identified in some patients who had undergone pyloromyotomy 5 to 7 years earlier. However, other studies have shown no differences between previous patients with PS and controls after a long-term follow-up.

### WHEN TO REFER

- All infants with PS should be referred to a surgeon.

### WHEN TO ADMIT

- All infants need to be hospitalized to correct the electrolyte imbalance and for surgery intervention.

## Chapter 322

# RENAL TUBULAR ACIDOSIS

Ronald Kallen, MD

### DEFINITION

Renal tubular acidosis (RTA) is not a single entity but a collection of complex disorders. RTA is the principal cause of hyperchloremic metabolic acidosis with a normal anion gap in an infant or child ingesting a typical diet who does not have gastroenteritis or chronic kidney disease (anion gap,  $\text{mEq/L} = [\text{Na}^+] - ([\text{Cl}^-] + [\text{HCO}_3^-])$ ). The term *tubular* means that metabolic acidosis is a consequence of a defect affecting tubular mechanisms for acid excretion. This is in contrast to metabolic acidosis arising from the underexcretion of acid caused by kidney failure or an increase in acid production, as

in diabetic ketoacidosis, lactic acidosis, or total parenteral nutrition, which typically cause an increase in the plasma anion gap. RTA is an impaired capacity of the kidney to excrete the usual daily load of acid arising from metabolism. Renal excretory function, as estimated by creatinine clearance, is relatively intact.

## CLINICAL MANIFESTATIONS

The diagnosis of RTA should be considered in any infant or young child with metabolic acidosis accompanying failure to thrive, recurrent vomiting, short stature, rickets, nephrocalcinosis, hypotonia, muscle weakness, sensorineural hearing loss, recurrent episodes of dehydration, kidney stones, gastroenteritis with incomplete recovery from metabolic acidosis, or a family member already known to have RTA. Failure to thrive during infancy is often the presenting feature of RTA. Growth is a complex process, and the molecular mechanisms of impaired growth in children with RTA are not completely understood. The impaired tubular phosphate reabsorption of Fanconi syndrome (a constellation of proximal tubular transport defects causing glucosuria, aminoaciduria, bicarbonaturia, and phosphaturia) contributes to rickets and short stature. Moreover, the buffering of hydrogen ion ( $H^+$ ) by bone causes the release of calcium ( $Ca^{2+}$ ) and consequent hypercalciuria, which contributes to osteopenia and short stature in certain forms of RTA. Metabolic acidosis inhibits osteoblasts and bone turnover. However, growth impairment is multifactorial and some children with Fanconi syndrome continue to lag in growth despite the correction of metabolic acidosis.

The diagnosis of metabolic acidosis is often based on the measurement of serum bicarbonate by a clinical laboratory autoanalyzer. One report found that the measurement by autoanalyzer tended to falsely estimate a reduction of serum bicarbonate concentration in contrast to estimation by a venous blood gas. RTA is often suspected in infants or young children with failure to thrive and a plasma bicarbonate level below the reference range. However, the monogenic forms of RTA are, in fact, rare disorders and are not found as often as they are suspected.

The serum potassium may be normal, low, or high. RTA associated with episodic hypokalemia may be accompanied by profound muscle weakness and, in rare instances, recurrent paralysis. In the absence of a blood gas analysis confirming acidemia, a venous blood carbon dioxide ( $CO_2$ ) content less than 20 mEq/L in an infant or young child with failure to thrive, in the absence of diarrhea, and accompanied by hyperchloremia and a normal anion gap, should raise suspicion of RTA, especially if the urine pH is 5.5 or higher.

RTA, in association with hyponatremia and hyperkalemia, can also present as an acute life-threatening event in some infants with a profound salt-losing condition and hypovolemia, such as pseudohypoaldosteronism (PHA) type 1 or salt-losing congenital adrenal hyperplasia. However, in these instances the physician is not dealing with “classic” RTA but metabolic acidosis as a secondary accompaniment of impaired mineralocorticoid receptor function or aldosterone deficiency.

RTA may present rarely as isolated “idiopathic” hypercalciuria or by passage of a kidney stone in a

child with incomplete RTA (impaired urinary acidification with normal plasma bicarbonate), which may be accompanied by a family history of nephrolithiasis in association with hypocitraturia. For some children in at-risk families, hypocitraturia may be the only indication of incomplete RTA.

The family history should be explored with questions regarding other affected family members in preceding generations or affected siblings of an individual with suspected RTA. In the instance of an apparent *de novo* occurrence of RTA, consanguinity may play a role. The occurrence of nephrolithiasis in other family members may be significant. A history of a sudden unexplained demise in a neonate suggests the possibility of a salt-losing condition that may be associated with RTA.

## PATHOPHYSIOLOGY

Genetic RTA syndromes in children occur because of mutations of genes encoding ion transporters that play a key role in the kidney's contribution to acid-base homeostasis. These rare conditions are primary monogenic disorders, have an autosomal-recessive mode of inheritance in most instances, and may be associated with ocular defects or hearing impairment. However, the physician is more likely to encounter secondary forms of RTA that result from drugs or acquired tubulointerstitial disease. Other instances of RTA are associated with another primary hereditary disorder, such as cystinosis, or from other causes of Fanconi syndrome. Moreover, a transient form of acquired RTA may occur in very low-birth-weight infants with delayed maturity of renal tubular function. RTA in adults may be associated with autoimmune disease and other conditions not generally encountered in children. These disorders will not be considered further in this chapter. In the evaluation of a child suspected of having RTA, the history should include inquiry about medications.

RTA is a consequence of a mismatch between the usual rate of acid production and the rate of renal acid excretion. The daily production of endogenous acid mainly arises from dietary protein, primarily sulfur-containing amino acids (methionine, cystine) that are not subsequently resynthesized into protein, ultimately yielding the strong mineral acid, sulfuric acid ( $H_2SO_4$ ). The accession of protons ( $H^+$ ) derived from  $H_2SO_4$  into the extracellular fluid is promptly buffered by bicarbonate ( $HCO_3^-$ ). Buffering by the extracellular pool of  $HCO_3^-$  only accounts for approximately one-half of the disposition of an acid load. In more chronic forms of metabolic acidosis, buffering of  $H^+$  by bone mineral is accompanied by the release of  $Ca^{2+}$ , hydroxyl ion ( $OH^-$ ), and phosphate ( $PO_4^{3-}$ ) from the hydroxyapatite crystal surface. During the rapid growth phase of infancy and early childhood, the accretion of calcium, phosphate, and hydroxyl ion into the hydroxyapatite crystal structure of bone also contributes to the endogenous acid load by the release of approximately 1 mEq of  $H^+$  for each milliequivalent of  $Ca^{2+}$  retained in bone.

The rate of endogenous acid production in infants and children, 2 to 3 mEq/kg/day, must be matched, milliequivalent for milliequivalent, by the excretion of  $H^+$  bound to the 2 principal urinary buffers, ammonia ( $NH_3$ ) and monohydrogen phosphate ( $HPO_4^{2-}$ ). Acid

excretion by the kidney is represented by the sum in the urine of  $\text{NH}_4^+$  and  $0.8 \times \text{H}_2\text{PO}_4^-$  (expressed as mEq). The multiplier 0.8 accounts for the 20% of serum phosphate that is in the form of dihydrogen phosphate,  $\text{H}_2\text{PO}_4^-$  at pH 7.40. The major adaptive response to an increasing acid load is an increase in ammonium ( $\text{NH}_4^+$ ) production and excretion in contrast to phosphate, which has a relatively fixed rate of excretion.  $\text{NH}_4^+$  production is regulated and can expand several-fold from baseline in acute metabolic acidosis, such as diabetic ketoacidosis. Metabolic acidosis accompanying newly recognized RTA is generally of intermediate severity and not catastrophic, which is in contrast to the acute metabolic acidosis occurring in some patients with overproduction of acid, as in diabetic ketoacidosis. The essential defect in all forms of RTA is a diminished ability to excrete  $\text{NH}_4^+$  in the face of the usual rate of acid production.

## RENAL MECHANISMS FOR EXCRETION OF ACID

The collection of disorders known as RTA are better understood after discussing the role of the kidney in maintaining acid–base balance. One principal aspect is the segmental topology of the nephron for the absorption and secretion of particular solutes and, in the context of RTA, especially the absorption of filtered sodium bicarbonate and the secretion of  $\text{H}^+$ .

The epithelial cells of the proximal tubule, thick ascending limb (TAL) of the loop of Henle, distal tubule, connecting tubule, and the cortical and medullary segments of the collecting duct are specialized for ion translocation against a gradient and ultimately require the expenditure of energy. These epithelia separate 2 fluid compartments: the lumen of the tubule and the interstitial fluid compartment of the kidney. The epithelial cells are polarized and have a distinct apical membrane facing the lumen and a distinct basolateral membrane interfacing the interstitial fluid compartment (see Figure 322-1). The apical and basolateral membranes meet at the tight-junction complexes between adjacent cells. Each membrane has a unique complement of ion-translocating mechanisms, either transporters anchored to the lipid bilayer of the cell membrane or ion-specific channels. An ion transporter is a membrane-associated protein, with a binding site for the specific ion to be translocated. The rate of translocation is regulated by the cycling of transporters and channels between the membrane and specialized structures in the cytosol. Some transporters perform primary active transport against an electrochemical gradient and have a catalytic site for the hydrolysis of adenosine triphosphate (ATP). The energy released from the high-energy phosphate bond is used to translocate an ion against an electrochemical gradient that would otherwise impede movement of the solute. These channels and transporters affect the distribution of electrical charges on either side of the membrane. If a transported ion is accompanied by an ion with an equivalent but opposite charge, then the transport activity is electroneutral. Other ion transport activities are electrogenic, resulting in an asymmetrical transepithelial distribution of charges. A notable

example of the latter relevant to this discussion of RTA is sodium ( $\text{Na}^+$ ) absorption via the apical epithelial sodium channel (ENaC) of principal cells in the aldosterone-sensitive distal nephron, which generates a lumen-negative potential and is a necessary precondition for  $\text{H}^+$  secretion in the distal nephron.

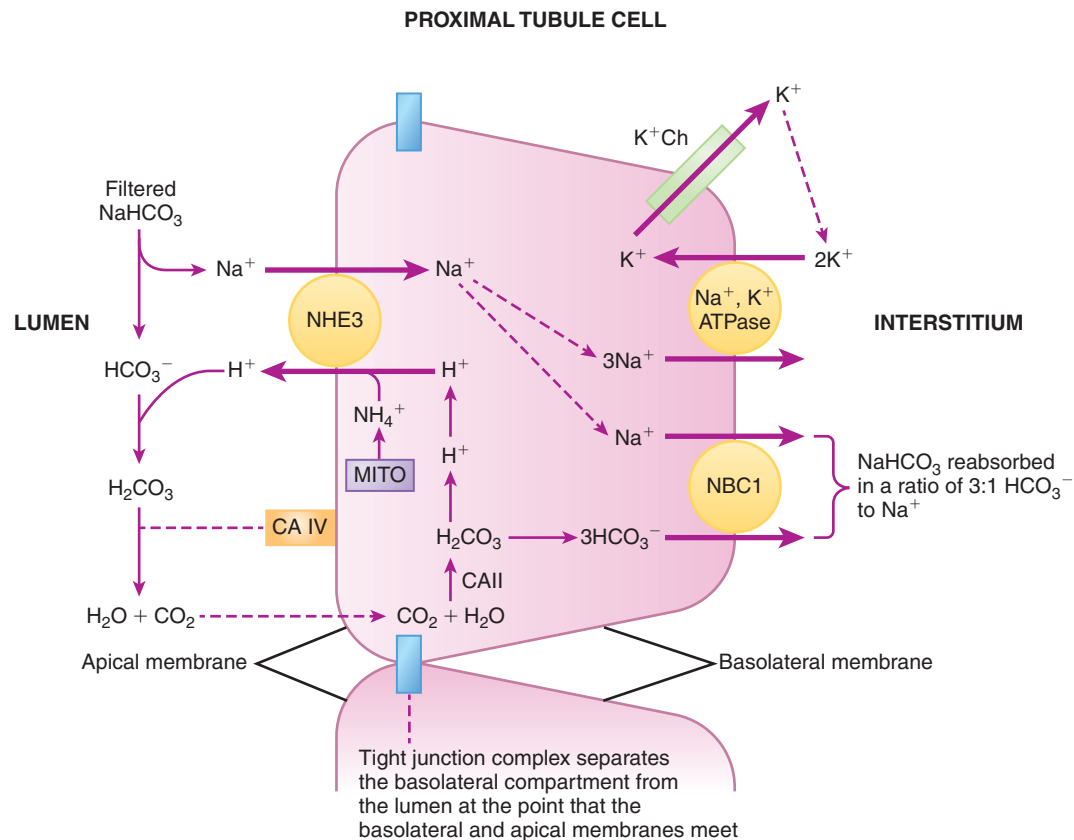

The role of the kidney in maintaining pH homeostasis principally involves 2 discrete processes in the handling of  $\text{HCO}_3^-$ : reclamation and regeneration of  $\text{HCO}_3^-$ . The first, reclamation, absorbs filtered  $\text{HCO}_3^-$  in proximal segments of the nephron, and the second, regeneration in the collecting duct, excretes  $\text{H}^+$  in the form of  $\text{NH}_4^+$  and dihydrogenphosphate ( $\text{H}_2\text{PO}_4^-$ ) and, in the process, generates “new”  $\text{HCO}_3^-$ . The task of reclaiming filtered  $\text{HCO}_3^-$  in the proximal tubule is mediated by  $\text{H}^+$  secretion in exchange for absorbed  $\text{Na}^+$  via the NHE3 exchanger in the lumen-facing membrane (see Figure 322-1). The process of  $\text{HCO}_3^-$  regeneration occurs in more distal segments of the nephron. The bulk of filtered  $\text{HCO}_3^-$ , approximately 80% to 90%, has already been absorbed by the reclamation process in more proximal segments. The remaining filtered  $\text{HCO}_3^-$  is absorbed mainly in the TAL. The task now for the collecting duct is to generate “new”  $\text{HCO}_3^-$ , which serves to replenish the pool of  $\text{HCO}_3^-$  and nonbicarbonate buffers that has had its stock depleted at a rate of 2 to 3 mEq/kg/day as buffer is consumed by  $\text{H}^+$  arising from metabolism. This process of  $\text{HCO}_3^-$  regeneration by the collecting duct is depicted in Figure 322-2, which shows that for every new  $\text{HCO}_3^-$  generated, a  $\text{H}^+$  is also generated *pari passu* by cytosolic carbonic anhydrase II (CA II) and is destined for excretion by an apical proton pump.

## AMMONIUM EXCRETION MECHANISM

All forms of RTA are ultimately caused by the inability of the kidney to maintain plasma  $\text{HCO}_3^-$  concentration at a physiologic level in the face of the usual rate of acid production. The role of the kidney in precisely aligning acid excretion with endogenous acid production is served mainly by  $\text{NH}_4^+$  generation and excretion. The other main urinary buffer,  $\text{H}_2\text{PO}_4^-$ , is a minor actor, because most of the filtered phosphate ( $\text{HPO}_4^-$  and  $\text{H}_2\text{PO}_4^-$ ) is absorbed proximally, and only about 15% to 20% is available for buffering in the collecting duct. The details of the multi-step process of  $\text{NH}_4^+$  excretion are complex. The following description sketches the main features of this process and refers mainly to  $\text{NH}_4^+$  since, in the range of pH between the renal interstitium and of the fluid in the tubular lumen, the equilibrium concentration of  $\text{NH}_3$  and  $\text{NH}_4^+$  is massively shifted in the direction of  $\text{NH}_4^+$  (at pH 7.4, over 98% of the total of  $\text{NH}_4^+$  and  $\text{NH}_3$  is  $\text{NH}_4^+$ ). The former paradigm of the terminal step of  $\text{NH}_4^+$  excretion as a process linked to the passive diffusion of  $\text{NH}_3$  into the lumen of the collecting duct and “trapping” of  $\text{NH}_4^+$  has been superseded by the recognition of a membrane transporter, RhCG, specialized for the translocation of  $\text{NH}_3$  from the medullary interstitium to the lumen of the collecting duct by the type A intercalated cell.

The process of  $\text{NH}_4^+$  excretion can be broken down into 4 steps (see Figure 322-3). First, ammoniogenesis occurs in the proximal tubule. The primary substrate is the amino acid, glutamine, which is transported

**Figure 322-1** Approximately 80% to 90% of filtered  $\text{HCO}_3^-$  is reabsorbed in the proximal tubule. The basolateral  $\text{Na}^+\text{K}^+$  ATPase maintains transmembrane gradients of  $\text{Na}^+$  and  $\text{K}^+$  that drive the apical  $\text{Na}^+\text{H}^+$  exchanger (NHE3) and the basolateral  $\text{Na}^+\text{HCO}_3^-$  cotransporter (NBC1). The reaction via cytosolic CA II,  $\text{CO}_2 + \text{H}_2\text{O} \rightarrow \text{H}_2\text{CO}_3 \rightarrow \text{H}^+ + \text{HCO}_3^-$ , cycles 3 times yielding 3  $\text{HCO}_3^-$  before NBC-1 is able to transport  $\text{HCO}_3^-$  and  $\text{Na}^+$  in a 3:1 ratio. Not depicted in the figure is an apical proton pump ( $\text{H}^+\text{-ATPase}$ ), which is responsible for a smaller proportion of  $\text{H}^+$  secretion and  $\text{HCO}_3^-$  absorption.  $\text{NH}_4^+$  is generated within mitochondria and secreted into the lumen after binding to the  $\text{H}^+$  site of the NHE3 exchanger. The production of  $\text{NH}_4^+$  is inhibited by hyperkalemia. Although not depicted, the apical membrane is arranged as a brush border with many infoldings, which provide a large surface area for bulk absorption of  $\text{Na}^+$  and  $\text{HCO}_3^-$ . CA II, cytosolic carbonic anhydrase II; CA IV, apical membrane carbonic anhydrase IV;  $\text{K}^+\text{Ch}$ , basolateral potassium ion channel; MITO, mitochondrion.

into the mitochondria of cells of the proximal tubule. The oxidative metabolism of 1 glutamine ultimately yields 2 each of  $\text{NH}_4^+$  and  $\text{HCO}_3^-$  in equimolar quantities. This newly formed  $\text{HCO}_3^-$  exits the proximal tubular cell via the basolateral NBC1 cotransporter (in a molar ratio of 1  $\text{Na}^+$  and 3  $\text{HCO}_3^-$ ) and exits the kidney in renal venous blood and becomes part of the extracellular  $\text{HCO}_3^-$  pool that is filtered and reclaimed (see Figure 322-1). This initial step is accomplished by the secretion of  $\text{NH}_4^+$ , in exchange for luminal  $\text{Na}^+$ , by  $\text{NH}_4^+$  occupying the  $\text{H}^+$  binding site on the apical  $\text{Na}^+\text{H}^+$  exchanger (NHE3; see Figure 322-1). Although this initial step has contributed to the restoration of the  $\text{HCO}_3^-$  pool, additional steps in the processing of  $\text{NH}_4^+$  must unfold before acid, in the form of  $\text{NH}_4^+$ , is actually excreted and new  $\text{HCO}_3^-$  is generated.

The second step in  $\text{NH}_4^+$  processing is its absorption in the TAL by occupying the  $\text{K}^+$  site on the apical  $\text{Na}^+\text{K}^+\text{2Cl}^-$  cotransporter (NKCC2; Figure 322-4). The

interstitial accumulation of  $\text{NH}_4^+$  constitutes the third step in the  $\text{NH}_4^+$ -excretion mechanism. The concentration of  $\text{NH}_4^+$  increases at each successively deeper stratum of the medulla, reaching the highest concentration toward the papilla. The mechanism by which  $\text{NH}_4^+$  exits the cells of the TAL is not yet known. Most of the reabsorbed  $\text{NH}_4^+$ , up to 80% of that ultimately excreted, is recycled to the medullary interstitium, where it is available for the fourth step.

The fourth step in the ammonium excretion mechanism is the transport of  $\text{NH}_4^+$  from the interstitium across the basolateral membrane of the type A intercalated cell of the collecting duct. At this membrane,  $\text{NH}_4^+$  dissociates, yielding  $\text{NH}_3$ , which is transported into the cytosol via the basolateral RhCG transporter, which is thought to function as a “gas channel.” The high concentration of  $\text{NH}_4^+$  in the medullary interstitium “feeds” the  $\text{NH}_3$  transporter, RhCG, in the basolateral membrane. The RhCG transporter is also present in the apical membrane. The intracellular  $\text{NH}_3$  is shuttled to

**Figure 322-2** The epithelium of the collecting duct is a mosaic of Na<sup>+</sup>-absorbing and K<sup>+</sup>-secreting principal cells and H<sup>+</sup>-secreting type A intercalated cells (not depicted in the latter is an apical H<sup>+</sup>,K<sup>+</sup>-exchanger that has a less important role in H<sup>+</sup> secretion than the apical H<sup>+</sup>-ATPase). The lumen-negative transepithelial potential difference is maintained by the aldosterone-stimulated apical epithelial Na<sup>+</sup> channel (ENaC) of the principal cell. The lumen negativity facilitates K<sup>+</sup> secretion by the apical K<sup>+</sup>-channel (ROMK) of the principal cells and H<sup>+</sup> secretion by the type A intercalated cells. A diminution of a lumen-negative electrical gradient is referred to as a *voltage defect*. The apical H<sup>+</sup>-ATPase and the basolateral Cl<sup>-</sup>,HCO<sub>3</sub><sup>-</sup>-exchanger (AE1) of the type A intercalated cell are each affected by loss-of-function mutations causing impaired HCO<sub>3</sub><sup>-</sup> regeneration and RTA. Aldosterone interacts with the mineralocorticoid receptor (MR) of the primary cell, which then translocates to the nucleus and after binding to a promoter region of DNA triggers upregulation of ENaC and Na<sup>+</sup>-K<sup>+</sup>-ATPase. NH<sub>3</sub> pooled in the medullary interstitium undergoes transcellular transport via the basolateral and apical RhCG “gas channels.” Hyperkalemic RTA arises secondary to aldosterone deficiency or unresponsiveness of the mineralocorticoid receptor. The consequent hyperkalemia inhibits NH<sub>4</sub><sup>+</sup> production by the proximal tubule. Principal cell: ENaC, epithelial Na<sup>+</sup> channel; K<sup>+</sup>Ch, basolateral K<sup>+</sup> channel; MR, mineralocorticoid receptor; ROMK, apical K<sup>+</sup> channel. Type A intercalated cell: Cl<sup>-</sup>Ch, basolateral Cl<sup>-</sup> channel; RhCG, basolateral and apical Rhesus C glycoprotein; not depicted, the basolateral Na<sup>+</sup>,K<sup>+</sup>-ATPase transporter.

the apical RhCG transporter for secretion. Once in the lumen, NH<sub>3</sub> is protonated with H<sup>+</sup> secreted by the apical H<sup>+</sup>-ATPase of the type A intercalated cell, driven by the lumen-negative potential created by sodium absorption via the ENaC channel of neighboring principal cells of the collecting duct. As the collecting duct courses from

cortex to the medulla, the most active segment for H<sup>+</sup> secretion is the inner medullary collecting duct. Thus, NH<sub>4</sub><sup>+</sup> excretion is ultimately accomplished by the coordinated action of 4 different cell types in different segments of the nephron: proximal tubule, TAL, and, in the collecting duct segment, the type A intercalated cell and

**Figure 322-3** Ammonium excretion is a 4-step process. Step 1 is the generation of ammonium ( $\text{NH}_4^+$ ) from glutamine in the mitochondria of cells of the proximal tubule.  $\text{NH}_4^+$  exits the cell of the proximal tubule after binding to the  $\text{H}^+$  site of the apical  $\text{Na}^+$ ,  $\text{H}^+$  exchanger (NHE3, Figure 322-1). The broad arrow in the figure labeled with the numeral 1 denotes a packet of  $\text{NH}_4^+$  leaving the proximal tubule and entering the descending thin limb of the loop of Henle (DTL). There is further net addition of  $\text{NH}_4^+$  to this packet as the DTL courses through deeper strata of the renal medulla and encounters the high concentration of interstitial  $\text{NH}_4^+$  produced by the reabsorption of  $\text{NH}_4^+$  in the thick ascending limb loop of Henle (TALH) (step 2). The mechanism of transport of interstitial  $\text{NH}_4^+$  into the lumen of the DTL is not known. The broad arrow labeled with the numeral 2 represents a packet of  $\text{NH}_4^+$  arriving at the TALH. Step 2 is the reabsorption of  $\text{NH}_4^+$  in the TALH by binding to the  $\text{K}^+$  site of the apical  $\text{Na}^+$ ,  $\text{K}^+$ ,  $2\text{Cl}^-$  cotransporter (NKCC2, Figure 322-4). Step 3 is the interstitial accumulation of  $\text{NH}_4^+$ . After absorption,  $\text{NH}_4^+$  exits the cells of the TALH by possibly binding to the  $\text{H}^+$  site of a basolateral  $\text{Na}^+$ ,  $\text{H}^+$  exchanger (not depicted in Figure 322-4). The net effect of this recycling of  $\text{NH}_4^+$  is to populate the medullary interstitium with a pool of  $\text{NH}_4^+$ , which “feeds” the uptake of  $\text{NH}_3$  from the interstitium by the type A intercalated cell, TAIC (also see Figure 322-2) via a basolateral RhCG transporter. The cytosolic  $\text{NH}_3$  is then shuttled to the apical RhCG transporter for secretion into the lumen of the medullary collecting duct, CD (also see Figure 322-2). Although not depicted in the above figure, RhCG transporters are also found in principal cells (PRNC) of the CD (also see Figure 322-2). Step 4 is the protonation of  $\text{NH}_3$  and “ion trapping” of  $\text{NH}_4^+$  in the lumen of the collecting duct. As  $\text{NH}_4^+$  (and the  $\text{NH}_3$ , which is in equilibrium with  $\text{NH}_4^+$ ) are removed by excretion, a gradient for continuing transport of  $\text{NH}_3$  from the medullary interstitium is maintained (broad, dotted arrow). The shading of the vertical arrow labeled *osmolality* denotes the increasing concentration of  $\text{NH}_4^+$  and other solutes in successively deeper layers of the medulla. CD, medullary collecting duct; DTL, descending thin limb of loop of Henle; PRNC, principal cell; PROX, proximal tubule; TAIC, type A intercalated cell; TALH, thick ascending limb of loop of Henle.

the principal cell. This is a regulated process, attuned to the demand for acid excretion by upregulation as demand increases. The net effect is that for each  $\text{NH}_4^+$  excreted a new  $\text{HCO}_3^-$  is returned to the extracellular pool. Thus, the  $\text{NH}_4^+$  originally produced by the proximal tubule, which was then reabsorbed in the TAL

to maintain the high interstitial concentration of  $\text{NH}_4^+$ , is now finally out of the body.

In the context of childhood RTA, each of the 4 steps of  $\text{NH}_4^+$  processing is implicated in the pathogenesis of the different forms of RTA. The initial step, proximal ammoniogenesis, is inhibited by hyperkalemia

**Figure 322-4** The thick ascending limb (TAL) is the “recycling center” of the kidney and provides for the pooling of  $\text{NH}_4^+$ ,  $\text{Na}^+$ ,  $\text{K}^+$ , and  $\text{Cl}^-$  in the medullary interstitium. It is the site of  $\text{NH}_4^+$  reabsorption by the apical  $\text{Na}^+$ - $\text{K}^+$ - $2\text{Cl}^-$  cotransporter (NKCC2). The lumen-directed  $\text{K}^+$  conductivity of the ROMK channel maintains a lumen-positive electrical gradient.  $\text{NH}_4^+$  binds to the  $\text{K}^+$  site of the transporter. This substitution is possible because both have a similar ionic radius. Recent data suggest that  $\text{NH}_4^+$  exits via a basolateral  $\text{Na}^+$ ,  $\text{H}^+$  exchanger [NHE4] by occupying the  $\text{H}^+$  site. As shown in the figure, a paracellular pathway driven by the lumen-positive electrical gradient adds to pooling of  $\text{NH}_4^+$  in the interstitium. The apical membrane has a low permeability to  $\text{NH}_4^+$ , which facilitates the medullary interstitial accumulation of  $\text{NH}_4^+$ . Cl-Ch, basolateral chloride channel; ROMK, apical  $\text{K}^+$  channel.

occurring in mineralocorticoid deficiency or mineralocorticoid unresponsive states. The second step in the TAL, absorption of  $\text{NH}_4^+$  by the NKCC2 cotransporter, is also impaired by hyperkalemia, because  $\text{K}^+$  in the lumen more effectively competes with  $\text{NH}_4^+$  for the same binding site on the transporter (see Figure 322-4). This impaired transport of  $\text{NH}_4^+$  affects the third step, the accumulation of  $\text{NH}_4^+$  in the medullary interstitium. Another disease process affecting this third step is inflammation and scarring of the inner medulla, distorting the specialized anatomy of the countercurrent multiplier system responsible for the increasing concentration of solutes and  $\text{NH}_4^+$  in the deeper strata of the medulla. Nephrocalcinosis, as a consequence of the treatment of the proximal tubule disorder X-linked hypophosphatemic rickets with vitamin D and phosphate supplement, is a cause of regeneration-defect RTA in some patients. Examples of disorders causing an acquired form of RTA include recurrent pyelonephritis with interstitial fibrosis affecting the renal papillae, obstructive uropathy, medullary sponge kidney, and sickle cell disease. The fourth and final step in  $\text{NH}_4^+$

excretion is also impaired in RTA and is the consequence of 2 different defects; either a  $\text{H}^+$  secretory defect or diminished lumen-negativity (see Figure 322-2). There is no known genetic mutation linked to an impairment of the RhCG translocator protein.

## CLASSIFICATION OF RENAL TUBULAR ACIDOSIS

This chapter introduces a classification of RTA based on the physiology of  $\text{HCO}_3^-$  transport rather than referencing nephron segments (“proximal” versus “distal”). The 2 basic processes of  $\text{HCO}_3^-$  handling described above serve as the basis for this physiologic classification into 2 main types of RTA: a reclamation-defect type and a regeneration-defect type (see Table 322-1). The reclamation-defect type is traditionally referred to as proximal RTA or type 2 RTA. Although the bulk of  $\text{HCO}_3^-$  absorption, 80% to 90%, occurs in the proximal tubule, reclamation is completed in more distal segments, and the term *proximal* RTA is not physiologically correct. Most reclamation-defect RTA disorders

**Table 322-1** Classifications of Renal Tubular Acidosis

PHYSIOLOGIC	CONVENTIONAL
Reclamation defect <ul style="list-style-type: none"> <li>• With Fanconi syndrome</li> <li>• Primary, nonsyndromic</li> </ul>	Type 2, proximal
Regeneration defect <ul style="list-style-type: none"> <li>• Nonhyperkalemic</li> <li>• Hyperkalemic <ul style="list-style-type: none"> <li>■ Acidification intact <ul style="list-style-type: none"> <li>○ Pseudohypoaldosteronism, 1a, 1b, 2</li> </ul> </li> <li>■ Acidification impaired <ul style="list-style-type: none"> <li>○ Medullary tubulointerstitial disease</li> </ul> </li> </ul> </li> </ul>	Type 1, distal  Type 4
Hybrid	Old type 3

in children are also accompanied by other defects localized to the proximal tubule, including impaired absorption of amino acids, glucose, and phosphate (Fanconi syndrome). Regeneration-defect RTA is traditionally referred to as distal RTA or type 1 RTA. The 2 subtypes of regeneration-defect RTA are nonhyperkalemic and hyperkalemic, the latter formerly also referred to as type 4 RTA (see Table 322-1). Another type of RTA has elements of both a reclamation defect and a regeneration defect. In Table 322-1, this is shown as Hybrid or Old type 3.

## TYPES OF RENAL TUBULAR ACIDOSIS

### Reclamation Defect

Reclamation-type RTA (type 2 or proximal RTA; see Table 322-2) is most commonly associated with Fanconi syndrome (aminoaciduria, glucosuria, phosphaturia,  $\text{HCO}_3^-$  wasting, and vitamin D-dependent rickets) of cystinosis. Although the gene defect in cystinosis has been described (OMIM [Online Mendelian Inheritance in Man] 219800, a mutation of *CTNS*, encoding cystinosisin, at locus 17p13), it is not known how the lysosomal accumulation of cystine causes Fanconi syndrome and RTA. One presumption is that the lysosomal accumulation of cystine somehow affects the generation of ATP by the mitochondria of the proximal tubule. Because ATP is the substrate for the basolateral  $\text{Na}^+, \text{K}^+$ -ATPase, which maintains a low intracellular  $\text{Na}^+$  concentration in the face of high transcellular trafficking of  $\text{Na}^+$ , it provides the driving force for  $\text{Na}^+$  absorption (in exchange for  $\text{H}^+$ ) and  $\text{Na}^+$ -coupled absorption of glucose, amino acids, and phosphate.

Urine pH in reclamation-type RTA may be appropriately acidic during acidemia, after the serum  $\text{HCO}_3^-$  in the absence of treatment has declined to approximately 12 to 15 mEq/L. If serum  $\text{HCO}_3^-$  levels are restored to normal during treatment with alkali (sodium or potassium citrate or sodium bicarbonate), then the impaired reclamation of filtered  $\text{HCO}_3^-$  in the proximal tubule results in the flooding of the distal nephron with  $\text{HCO}_3^-$ -rich fluid of alkaline pH. If luminal pH is

relatively alkaline, then  $\text{HPO}_4^{2-}$  and  $\text{NH}_3$  are not effectively protonated because the titration of  $\text{HPO}_4^{2-}$  by secreted  $\text{H}^+$  is mitigated by the reaction of protons with  $\text{HCO}_3^-$  in the lumen. After  $\text{HCO}_3^-$  replacement is stopped, the serum  $\text{HCO}_3^-$  concentration declines to a level that brings the filtered load of  $\text{HCO}_3^-$  into alignment with the proximal tubular capacity for reclamation. The TAL and distal tubule are no longer overwhelmed by a flood of alkaline fluid. Filtered  $\text{HCO}_3^-$  is now effectively reclaimed, and “new”  $\text{HCO}_3^-$  regeneration proceeds in the collecting duct unimpeded by the high luminal pH that existed during  $\text{HCO}_3^-$  wasting. Under this acidemic condition, the urine pH is in the acid range, and net acid excretion, mainly as  $\text{NH}_4^+$ , matches the rate of endogenous acid production such that underexcretion of  $\text{H}^+$  no longer occurs. However, the trade-off is a low plasma  $\text{HCO}_3^-$  and pH and the consequent effects on growth and bone mineral content of acidemia. Replacement of  $\text{HCO}_3^-$  restores plasma pH to normal, but massive  $\text{HCO}_3^-$  wasting ensues, requiring high doses of alkali, which may exceed 10 mEq/kg/day.

A Fanconi syndrome may also be acquired as a consequence of nephrotoxic injury from drugs such as aminoglycosides, valproate, 6-mercaptopurine, cisplatin, ifosfamide, and expired tetracycline. However, rickets or osteomalacia may occur as a consequence of the phosphate-wasting of Fanconi syndrome and impaired conversion by the proximal tubule cell of 25-hydroxy vitamin  $\text{D}_3$  to the biologically active form, 1,25-dihydroxy vitamin  $\text{D}_3$ , as a consequence of acidosis.

Reclamation-defect RTA also occurs in other genetic disorders associated with Fanconi syndrome, including galactosemia, tyrosinemia, Wilson disease, Lowe (oculocerebrorenal) syndrome, Dent tubulopathy of the subtype resulting from *OCRL* mutation, hereditary fructose intolerance, and glycogen storage disease type 1. It also may be acquired as a consequence of nephrotoxic injury that results from drugs such as outdated tetracycline, aminoglycosides, valproate, 6-mercaptopurine, cisplatin, and ifosfamide (see Table 322-2) or heavy metals, such as lead, mercury, or cadmium. Reclamation-defect RTA has also been reported in association with vitamin D deficiency and renal transplantation. Some patients with a syndromic mitochondrial disorder, such as Kearns-Sayre syndrome, may have a reclamation defect.

An autosomal-recessive inheritance of reclamation-type RTA without Fanconi syndrome (OMIM 604278) and associated with intellectual disability and ocular abnormalities (cataracts, corneal opacities, glaucoma, band keratopathy) is the result of a loss-of-function mutation of *SLC4A4* encoding the basolateral  $\text{Na}^+/\text{HCO}_3^-$  (NBC1) cotransporter (see Figure 322-1) of the proximal tubule. The gene has been mapped to locus 4q21 (see Table 322-3). This cotransporter is also found in ocular tissues. This is an exceedingly rare condition.

Isolated nonsyndromic reclamation-defect RTA is very rare. An autosomal-dominant form results from a mutation of *SLC9A3*, encoding the proximal cell apical membrane NHE3 exchanger (not shown in Table 322-3).

**Table 322-2** Drugs Associated With Acquired Renal Tubular Acidosis

AD, autosomal dominant; AE1, Cl<sup>-</sup>, HCO<sub>3</sub><sup>-</sup> exchanger; AR, autosomal recessive; ATPase, adenosine triphosphatase; CA, carbonic anhydrase; ENaC, epithelial sodium channel; NBC1, Na<sup>+</sup>, 3HCO<sub>3</sub><sup>-</sup> cotransporter, proximal tubule; OMIM, Online Mendelian Inheritance in Man; PHA, pseudohypoaldosteronism; RTA, renal tubular acidosis.

A reclamation-type RTA may also occur sporadically in infants, often of very low-birth-weight. This entity occurs infrequently. In one report, affected infants were usually boys and most no longer required alkali treatment after the passage of up to 8 years. Treatment with high doses of alkali (10–15 mEq/kg/day) resulted in marked improvement in growth. The serum HCO<sub>3</sub><sup>-</sup> concentration (or threshold) at which HCO<sub>3</sub><sup>-</sup> began to appear in urine ranged between 17.5 and 20 mEq/L, whereas in healthy infants and young children the lower limit of the HCO<sub>3</sub><sup>-</sup> threshold

is a serum concentration of about 22 mEq/L. In addition to failure to thrive, infants with this transient disorder may also experience recurrent vomiting. It may be speculated that this entity results either from a transient insufficiency of the basolateral NBC1 cotransporter or the apical NHE3 exchanger in the proximal tubule.

Reclamation-defect RTA may also occur in association with medications (see Table 322-2). Some of the medications listed in the table are also associated with multiple proximal tubular transport defects (Fanconi syndrome).

The treatment of reclamation-defect RTA with sodium bicarbonate, sodium citrate, or potassium citrate requires large doses to maintain serum  $\text{HCO}_3^-$  in the reference range, and at this level, urinary excretion of  $\text{HCO}_3^-$  approaches 10% to 15% of the filtered load. The dose required to compensate for this high rate of urinary loss, coupled with impaired  $\text{HCO}_3^-$  regeneration (2–3 mEq/kg/day), may approach 10 to 20 mEq/kg/day.

### Nonhyperkalemic Regeneration Defect

Regeneration-defect RTA refers to an impaired ability to generate “new”  $\text{HCO}_3^-$ . It is “new”  $\text{HCO}_3^-$  because reclamation has completely absorbed filtered  $\text{HCO}_3^-$  in nephron segments proximal to the collecting duct. The basic defect in the nonhyperkalemic form is a low rate of  $\text{H}^+$  secretion because of genetic mutations affecting transporters in the collecting duct. In this nephron segment aldosterone-responsive principal cells coexist in a mosaic with type A intercalated cells. Unlike reclamation-defect RTA, the rate of urinary loss of  $\text{HCO}_3^-$  is much lower, generally less than 5% of the filtered load (Table 322-4).

There are 2 forms of regeneration-defect RTA with autosomal-recessive inheritance that are associated with mutations of genes encoding different subunits of the apical proton pump of the type A intercalated cell (see Table 322-3). The proton pump, an  $\text{H}^+$ -ATPase, is a complex multimeric protein assembled from at least 13 subunits. The kidney-specific isoform of  $\text{H}^+$ -ATPase has 2 subunits implicated in autosomal-recessive RTA: the B1 and the a4 subunits. RTA with a defect in the B1 subunit is associated with sensorineural hearing loss (see Table 322-3, OMIM 267300) and is attributed to a mutation of *ATP6V1B1* at locus 2p13.3. The B1 subunit is a component of the catalytic site that hydrolyzes ATP. The sensorineural hearing deficit is evident early in life and may at first manifest as delayed language development. The *ATP6V1B1* gene is also expressed in the cochlea, and presumably the homozygous expression of the mutant alleles accounts for the hearing impairment.

A second form of autosomal-recessive regeneration-defect RTA with mild or later-onset hearing impairment in some individuals (see Table 322-3, OMIM 605239) is the result of a mutation of *ATP6V0A4* at locus 7q33-34, which encodes the a4 subunit of the apical proton pump. This gene is also expressed in the inner ear. The a4 subunit is important for both assembly of the pump and its ATPase activity.

A rare form of regeneration-type RTA has a pattern of autosomal dominant inheritance and is caused by a mutation of *SLC4A1* (OMIM, 179800, 109270, locus, 17q21-22) encoding the basolateral AE1 exchanger (see Table 322-3, Figure 322-2). An autosomal-recessive form consequent to the same mutation has a more severe phenotypic expression.

These rare primary types of RTA are typically associated with impaired growth progress, polyuria, hypercalciuria, nephrocalcinosis, nephrolithiasis, and hypokalemia. Because of impaired concentrating ability, infants are susceptible to the rapid development of severe dehydration in the event of diarrheal illness or protracted vomiting. The tendency to hypovolemia as a consequence of impaired urinary concentrating

ability stimulates aldosterone release, contributing to hypokalemia. Medullary nephrocalcinosis is apparent early in infancy and is readily detected on ultrasound examination as hyperechoic medullary regions. The further accumulation of calcium deposits may lead to chronic kidney disease in later years if acidosis is not adequately treated. Nephrocalcinosis may also interfere with the medullary recycling of  $\text{NH}_4^+$  and contribute to impairment of  $\text{NH}_4^+$  excretion. Nephrocalcinosis is attributed to hypercalciuria (calcium excretion  $>4$  mg/kg/day) and the latter is a consequence of the release of calcium from bone under the stimulus of metabolic acidosis. Enhanced proximal tubular absorption of citrate during acidosis and the consequent diminished rate of citrate excretion contribute to nephrocalcinosis.

Long-standing untreated, or inadequately treated RTA, and consequent buffering of  $\text{H}^+$  by bone mineral, release of calcium from bone, and hypercalciuria may cause decreased bone mineral density and increased risk of fracture. A baseline assessment of bone mineral density and subsequent periodic follow-up should be included in the long-term management plan. The periodic assessment of bone health also includes measurement of vitamin D status (25-hydroxycholecalciferol).

Some infants with primary regeneration-type RTA may also have a transient phase of impaired  $\text{HCO}_3^-$  reclamation and  $\text{HCO}_3^-$  wasting, requiring large doses of alkali. This hybrid type was once referred to as type 3 RTA. The reclamation defect subsides during childhood and the phenotype of regeneration-type RTA emerges. This presumed defect of  $\text{HCO}_3^-$  reclamation has not been characterized and it is not known which transporter in the proximal tubule cell may be affected.

Another variant of regeneration-type RTA is associated with a preserved ability to lower urine pH despite a low absolute rate of  $\text{H}^+$  secretion, resulting in a diminished accumulation of  $\text{CO}_2$  in urine (and a low urinary  $\text{CO}_2$  partial pressure [ $\text{PCO}_2$ ]) during bicarbonate administration. The low urine-to-blood  $\text{PCO}_2$  gradient has been interpreted as a rate-limited defect consequent to a presumed diminished rate of secretion of  $\text{H}^+$  in the collecting duct. However, this entity may simply be a milder expression of a primary secretory defect resulting from partial impairment of the apical  $\text{H}^+$ -ATPase. Nevertheless,  $\text{H}^+$  secretion is sufficient to establish a steep transtubular  $\text{H}^+$  gradient. Consequently, urine pH alone cannot be relied upon for the diagnosis of RTA because individuals with a rate-limited defect will not be identified without assessing the urine-to-blood  $\text{PCO}_2$  gradient (see Table 322-4,  $(\text{U} - \text{B}) \text{PCO}_2$ ).

The obverse of the rate-limited defect is ‘incomplete’ regeneration-type RTA. In this instance, blood acid-base status is normal but urinary acidification is impaired and a minimum urine pH less than 5.5 is not achieved. This condition has been implicated in adults with nephrolithiasis. Kidney stone passage was the first clue to a diminished rate of  $\text{H}^+$  secretion in the collecting duct. A recent report of an affected family with nephrolithiasis, hypocitraturia, and alkaline urine in heterozygotes with a mutation of 1 *ATP6V1B1* allele indicates that the B1 product of the normal allele is a functional component of the  $\text{H}^+$ -ATPase transporter.

Table 322-4  
Comparison of Reclamation Defect–Type Renal Tubular Acidosis and Regeneration Defect–Type Renal Tubular Acidosis

PARAMETER	RECLAMATION DEFECT		REGENERATION DEFECT	
	DURING ACIDEMIA	AFTER TREATMENT OF ACIDEMIA	NON HYPERKALEMIC	HYPERKALEMIC
Urine pH minimum	<5.5	>5.5	>5.5	>5.5
UAG	Negative	Not reliable	Positive	Positive
NH <sub>4</sub> <sup>+</sup> excretion	Decreased	Normal	Decreased	Decreased
Plasma K <sup>+</sup>	Normal or decreased	Normal or decreased	Normal or decreased	Increased
Fractional excretion of HCO <sub>3</sub> <sup>–</sup> as percentage of filtered load	<5	>10–15	<5	<5
(U – B) PCO <sub>2</sub> (mm Hg)	>20	—	<20	>20
Ca <sub>2</sub> <sup>+</sup> excretion	Normal	Normal	Increased	Normal or decreased
Citrate excretion	Normal	Normal	Decreased	Normal
Nephrocalcinosis, nephrolithiasis, or both present	Not present	Not present	Common	Not present
Bone disease	Rickets or osteomalacia	Rickets or osteomalacia	Rickets or osteomalacia	Rickets or osteomalacia
Alkali dose (mEq/kg/day)	10–20	10–20	5–8 (infancy), 3–4 (children)	5–8 (infancy), 3–4 (children)
				Not needed if response to fludrocortisone is adequate

B, blood; RTA, renal tubular acidosis; U, urine; UAG, urinary anion gap; (U – B) PCO<sub>2</sub>, partial pressure of CO<sub>2</sub> gradient between urine and blood.

The authors report that the expression of the normal allele is not negated by the mutant allele and that the milder phenotype of the haplo-insufficient state may explain some cases of calcium nephrolithiasis in individuals with a normal plasma  $\text{HCO}_3^-$  not suspected of having RTA.

Incomplete regeneration-defect RTA has been shown to affect height in boys with posterior urethral valves, normal estimated glomerular filtration rate, and normal acid-base status but impaired urinary acidification after challenge with  $\text{NH}_4\text{Cl}$ . The genetic conditions previously mentioned do not account for all instances of monogenic RTA. There may be up to 20% of primary RTA that has not yet been associated with a specific genetic defect. Moreover, instances of RTA without a known gene defect affecting a transporter may, in fact, be the result of mutations of modifier genes, or genes encoding transcription factors or proteins, involved in the trafficking of transporters to the cell membrane from sites of synthesis within the cell. Moreover, a mutation may not alter the structure or function of a transporter but may affect membrane targeting.

Acquired defects of acidification may occur when the renal medulla of both kidneys has sustained injury or distortion because of diffuse post-pyelonephritic scarring, sickle cell disease, obstructive hydronephrosis, nephrocalcinosis, and medullary sponge kidney.

The nonheritable occurrence of regeneration-defect RTA may also be associated with medications, such as amphotericin B and lithium (see Table 322-2). This may be encountered in medically complex patients receiving chemotherapy for cancer or certain antibiotics as prophylaxis while immunosuppressed.

Hypocitraturia is common in children with a regeneration-defect RTA and contributes to the susceptibility to nephrolithiasis and nephrocalcinosis. Citrate is the predominant urinary organic anion. It acts as an inhibitor of calcium stone formation by chelating ionized calcium as a soluble complex of calcium citrate, thereby lowering the supersaturation index of calcium oxalate or calcium phosphate. Filtered citrate, which exists as the tricarboxylate anion at physiologic pH, is preferentially absorbed as the dicarboxylate anion by an apical  $\text{Na}^+$ -dependent transporter in the proximal tubule. Urinary citrate reflects the proportion of filtered citrate that is not absorbed and is influenced by the state of acid-base balance. Absorption is enhanced by acidosis, which accounts for hypocitraturia in nonhyperkalemic regeneration-type RTA. Hyperkalemia suppresses the apical dicarboxylate transporter, possibly accounting for the normal-to-high urinary citrate and protection against nephrolithiasis in the hyperkalemic form of RTA. Hypokalemia enhances proximal citrate absorption and must be corrected if hypocitraturia is to be prevented or effectively treated. In healthy children between 3 and 15 years, the random urine citrate-to-creatinine ratio ranges between 127 and 300 mg/g creatinine or 75 to 177  $\text{mcmol/mM}$  of creatinine. The lower limit of the reference range of citrate excretion is  $180\text{mg}/1.73\text{m}^2$  in healthy males and  $250\text{mg}/1.73\text{m}^2$  in females based on a recent study of urinary citrate excretion, which showed both age and gender dependence. It is useful to monitor urinary

citrate excretion and the supersaturation indices of calcium oxalate and calcium phosphate in 24-hour urine collections during treatment with citrate to assess its efficacy.

Hypokalemia is common in regeneration-defect RTA and in some patients it may be severe and cause marked muscle weakness. The occurrence of hypokalemia does not seem to depend on a particular genetic subtype, but is more pronounced in autosomal-recessive regeneration-defect RTA. Amiloride, an inhibitor of the principal cell ENaC transporter, has been used to ameliorate the potassium wasting by diminishing the lumen-negative potential in the collecting duct.

### Hyperkalemic Regeneration Defect

There are 2 subtypes of hyperkalemic regeneration-defect RTA listed in Table 322-3. One subtype has an intact ability to acidify urine; the second subtype resembles the classic regeneration-type RTA in its inability to establish a steep  $\text{H}^+$  gradient by lowering urine pH to less than 5.5. In each instance, hyperkalemia suppresses both the production of  $\text{NH}_4^+$  in the proximal tubule and the transport of  $\text{NH}_4^+$  from the lumen of the TAL to the medullary interstitium.

The subtype with intact acidification is associated with rare hereditary conditions, including pseudo-hypoaldosteronism (PHA, type 1a and type 1b). The unresponsiveness of the principal cell of the collecting duct to aldosterone causes diminished lumen negativity that is normally generated by the ENaC channel. As a consequence,  $\text{K}^+$  secretion by the principal cell and  $\text{H}^+$  secretion by the type A intercalated cell are impaired. The diminution of lumen negativity (also referred to as a “voltage defect”) can also occur if there is decreased delivery of  $\text{Na}^+$  from the distal tubule to the collecting duct. The net effect of diminished  $\text{H}^+$  secretion is that accumulation of  $\text{NH}_4^+$  in the lumen of the medullary collecting duct is also diminished. The low rate of  $\text{H}^+$  excretion as  $\text{NH}_4^+$  results in metabolic acidosis, but the proximate causes are diminished lumen negativity, impaired  $\text{K}^+$  secretion, and hyperkalemia. The latter, in turn, suppresses  $\text{NH}_4^+$  generation by the proximal tubule. However, sufficient capacity remains for  $\text{H}^+$  secretion in the inner medullary collecting duct to achieve a urine pH less than 5.5. The impaired lumen negativity limiting  $\text{H}^+$  secretion by the apical proton pump may be partially offset by acidosis-induced upregulation of the apical  $\text{H}^+/\text{K}^+$ -ATPase of the type A intercalated cell (this transporter is not shown in Figure 322-2).

Most primary hyperkalemic RTA is caused by PHA type 1, which includes 2 main subtypes (1a and 1b). The renal-limited, or classic subtype (PHA, type 1a, OMIM 177735, 600983), has autosomal-dominant inheritance of a mutant *MLR* gene at locus 4q31.1, encoding the mineralocorticoid receptor (MR) protein (see Table 322-3). Phenotypic expression is highly variable. A severe salt-losing condition in neonates may result in death. Adults may have normal electrolytes and have an increased plasma aldosterone as the only manifestation of the disorder. Some children have a relatively mild disorder and are readily managed with salt replacement and alkali. In some instances, treatment is not needed beyond childhood, suggesting that

upregulated expression of the nonmutated allele has compensated for the haploinsufficient state by increasing the production of the functional MR protein. Some individuals without a history of affected family members may have a *de novo* mutation. The severe neonatal phenotype of PHA type 1a with salt wasting, hyponatremia, hyperkalemia, vomiting, dehydration, and metabolic acidosis resembles salt-losing congenital adrenal hyperplasia because of hypoaldosteronism consequent to adrenal 21-hydroxylase deficiency, an autosomal-recessive disorder.

The second subtype of PHA type 1 is an autosomal-recessive systemic disorder with multiple target organ defects (PHA type 1b, OMIM 269350) and is a consequence of a mutation affecting any 1 of the 3 genes encoding separate subunits of the ENaC channel protein (see Table 322-3). ENaC is also expressed in the lung, sweat glands, salivary glands, and colon. The concentrations of  $\text{Na}^+$  and  $\text{Cl}^-$  are increased in sweat, and because respiratory symptoms may also be present, this disorder may be confused with cystic fibrosis. The lung ENaC is active in the immediate postnatal period in clearing fluid from the lung, but instances of neonatal respiratory distress syndrome attributable to the systemic subtype of PHA type 1 have not been well documented. This disorder may also present with profound salt-wasting, hypovolemia, and metabolic acidosis, mimicking congenital adrenal hyperplasia. After the electrolyte abnormalities have been treated with salt and alkali, recurrent respiratory infections may dominate the clinical course during infancy. This subtype does not have a spontaneous remission and treatment is lifelong.

Some very low-birth-weight infants with a PHA type 1 phenotype may not actually have a heritable disorder but rather transient insufficiency or hyporesponsiveness of the MR protein to aldosterone. An entity referred to as “early childhood hyperkalemia” may be a consequence of the delayed appearance of MRs, resulting in impaired lumen negativity in the collecting duct. However, it is not associated with the severe sodium wasting and hypovolemia seen in typical neonatal PHA type 1. Plasma renin and aldosterone may be normal or high. This variant seems to be self-limited but, though hyperkalemia persists (serum  $\text{K}^+$  consistently  $>5.5$  mEq/L), it can be treated with furosemide to promote urinary  $\text{K}^+$  loss or with oral administration of a sodium polystyrene sulfonate resin that binds  $\text{K}^+$ . Infant formula can be depleted of  $\text{K}^+$  by adding the resin and then providing the supernatant for oral ingestion.

Another rare form of hyperkalemic regeneration-defect RTA is familial hyperkalemic hypertension, or PHA type 2A (OMIM 145260). This autosomal-dominant condition may not be diagnosed until adolescence or adulthood and is also known as Gordon syndrome or chloride shunt syndrome. Hyperabsorption of  $\text{Na}^+$  and  $\text{Cl}^-$  in the distal tubule by the thiazide-sensitive  $\text{Na}^+, \text{Cl}^-$ -cotransporter (NCCT), results in hypervolemia and low-renin hypertension. The consequent decreased delivery of  $\text{Na}^+$  to the principal cells of the collecting duct limits the ability to generate a lumen-negative potential and diminishes the driving force for  $\text{H}^+$  and  $\text{K}^+$  secretion. Although it typically occurs in adolescents and adults, it may also appear in neonates. This syndrome is known as Spitzer-Weinstein syndrome. A

low dose of a thiazide diuretic is effective treatment of the hypertension and hypervolemia. The increased delivery of  $\text{Na}^+$  to the collecting duct after beginning treatment with a thiazide enables lumen negativity, promoting  $\text{H}^+$  and  $\text{K}^+$  secretion and correcting both the metabolic acidosis and hyperkalemia. This diagnosis should be considered in a family with early-onset hypertension and hyperkalemia. There is genetic heterogeneity of this hyperkalemia-hypertension syndrome, including a mutation of *WNK1* (locus 12p13) or a mutation of *WNK4* (locus 17q21-22, see Table 322-3). The loss-of-function mutations of either of these genes results in upregulation of the activity of the NCCT protein.

Another clinical subtype of hyperkalemic RTA with impaired acidification may be associated with acquired renal parenchymal damage caused by recurrent pyelonephritis, obstructive uropathy, or sickle cell disease. The parenchymal damage may interfere with aldosterone binding to its receptor, as well as the medullary recycling of  $\text{NH}_4^+$ . Acidification by the inner medullary collecting duct may be impaired in these chronic tubulointerstitial nephropathies, and urine pH is generally above 5.5.

Other nonheritable causes of hyperkalemic regeneration-defect RTA are, in rare instances, from medications (see Table 322-2), such as inhibitors of the renin-angiotensin system (angiotensin-converting enzyme inhibitors or angiotensin-receptor blockers). In some instances, RTA is the expected consequence of the pharmacologic action of a medication. For example, amiloride, triamterene, and trimethoprim inhibit the ENaC of the principal cell. The aldosterone antagonists, spironolactone and eplerenone, bind to the MR and indirectly cause impaired lumen negativity by downregulation of the aldosterone-dependent ENaC channel.

Calcineurin inhibitors (cyclosporine or tacrolimus) have been implicated in causing mild metabolic acidosis and hyperkalemia after solid organ transplantation (see Table 322-2). The mechanism seems to be impaired responsiveness of the MR or acquired hypoaldosteronism that results from a hyporeninemic state. This condition responds to fludrocortisone.

A child with edema from nephrotic syndrome or hepatic cirrhosis who is not receiving diuretics may not have sufficient delivery of  $\text{Na}^+$  to the collecting duct to maintain lumen negativity, although this is rare. In essence, this is an acquired form of hyperkalemic regeneration-defect RTA.

### Hybrid

The hybrid type of RTA is rare and was once referred to as type 3 RTA. One well-characterized entity is marble bone disease (Guibaud-Vainsel syndrome), a rare autosomal-recessive disorder, which has elements of both  $\text{HCO}_3^-$  wasting (a reclamation defect) and impaired acidification (a regeneration defect). The cytosolic enzyme, CA II, is present in both the cells of the proximal tubule and the type A intercalated cells of the collecting duct. CA II is also present in osteoclasts. A bi-allelic loss-of-function mutation of *CA2* at locus 8q22 (OMIM +259730) has been identified in children with failure to thrive, osteopetrosis, cerebral calcifications, and mental impairment (see Table 322-3). Most reports

are of children of Arab ethnicity and in many instances there is a history of consanguinity. Osteoclastic resorption of bone is dependent on  $H^+$  secretion at the osteoclast–bone mineral interface. The impairment of osteoclast activity that occurs as a result of a deficiency of CA II causes low bone turnover, osteopetrosis, and an increased susceptibility to fractures. The dose of alkali required to correct the metabolic acidosis is comparable to that for reclamation-defect RTA. Medications inhibiting CA II and CA IV, such as acetazolamide, sulfonamides, or topiramate, are rare nonheritable causes of a hybrid RTA (see Table 322-2). Since cytosolic CA II is expressed widely in the kidney, it is especially susceptible to carbonic anhydrase inhibitors.

### Delayed Maturity

The concept that delayed development of certain discrete tubular functions may account for a self-limited form of RTA is discussed under the presumption that there is a delay in maturation of these functions during infancy. The phenotype, whether reclamation-defect RTA, regeneration-defect RTA, or an RTA with elements of both defects, is variable depending on which function lags in development. This presumption is not yet supported with data as to genetic controls of the maturation program of kidney development.

Some infants with failure to thrive and acidosis are suspected of having RTA and referred for further evaluation. Because the kidney is not an excretory organ during intrauterine life, glomerular filtration rate and tubular functions are low in the immediate newborn period. The postnatal maturation of tubular transport functions is load-driven, but the capacity to augment function in response to the excretory load may lag in some infants. Some very low-birth-weight infants may have a lower renal  $HCO_3^-$  threshold (the plasma concentration at which  $HCO_3^-$  begins to appear in urine), maintaining a steady-state serum  $HCO_3^-$  as low as 17 to 19 mEq/L. As mentioned in the Reclamation Defect section, some infants with recurrent vomiting and failure to thrive seem to have a delay in the development of the reclamation mechanism, which eventually resolves. None of the infants with recurrent vomiting and failure to thrive referenced above had Fanconi syndrome. The presumption is that this reclamation defect is a consequence of a delay in the emergence of a full complement of either NHE3 or NBC1 transporters in the proximal tubule.

In addition to a reclamation defect, some very low-birth-weight infants may also have an impaired ability to conserve  $Na^+$ . This impairment may represent an inability of the distal nephron to respond to aldosterone, perhaps because of a delay in the emergence of an adequate complement of MRs, analogous to the renal subtype of PHA type 1. Moreover, the impaired response to aldosterone may also lead to hyperkalemia and its consequent inhibition of  $NH_4^+$  production in the proximal tubule, which may persist during the first few years of life. The impaired response to aldosterone in infants in the first few months of life may explain the somewhat higher reference range (mean  $\pm$  standard deviation) for plasma  $K^+$ ,  $5.2 \pm 0.8$  mEq/L. A reasonable presumption is that, in addition to an impaired response to aldosterone, delayed

maturation of either the  $H^+$ -ATPase or the AE1 transporter of the type A intercalated cell may produce a transient  $HCO_3^-$  regeneration defect in some infants. Thus, this type of RTA, a consequence of delayed maturity rather than a genetic mutation, is also a hybrid disorder in some infants and has elements of both  $HCO_3^-$  reclamation and regeneration defects. The risk for RTA is further amplified in low-birth-weight infants with nephrocalcinosis as a consequence of furosemide treatment, resulting in impaired accumulation of  $NH_4^+$  in the medullary interstitium. However, not all infants with a low serum  $HCO_3^-$  should be diagnosed as delayed-maturity RTA if they are not acidemic and are gaining weight. These infants may simply have a transiently lowered tubular threshold for  $HCO_3^-$  excretion. In fact, it may be “physiologic” to maintain a somewhat lower steady state concentration of serum  $HCO_3^-$ , since the intake of breast milk or humanized formula is less acidogenic owing to the relatively low protein content.

### Acquired Renal Tubular Acidosis

The genetic forms of RTA are rare. It is more likely that the primary care physician will encounter RTA caused by drugs affecting transporters in certain segments of the nephron. Many drugs have been implicated, but Table 322-2 displays a selected list in relation to the affected mechanism of  $HCO_3^-$  handling. Generally, drug-induced RTA is reversible after cessation of the offending drug unless tubulointerstitial fibrosis has supervened.

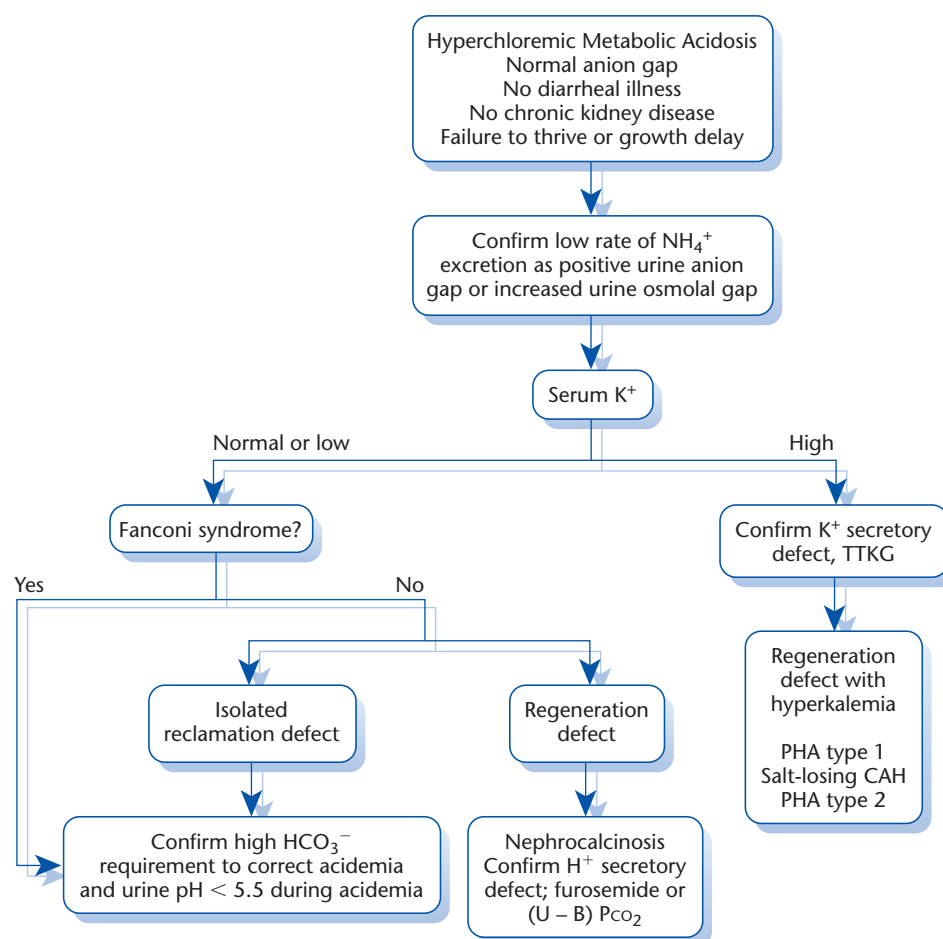

### EVALUATION

The comprehensive evaluation of suspected RTA entails studies with access to a clinical laboratory working in close collaboration with a nephrologist. However, the physician can perform several simple tests. One pathway of decision making for a systematic evaluation is depicted in an algorithm and includes elements of history and physical examination in addition to biochemical findings (see Figure 322-5). The initial presentation of RTA is often that of an infant or young child with failure to thrive. There are many causes of failure to thrive, including disorders that are not primary renal disorders. The initial screening should include an assessment of thyroid function and bone age and other tests appropriate for a possible nonrenal etiology of failure to thrive.

Once it is established that the patient has a renal etiology for hyperchloremic metabolic acidosis, the principal assessment is an estimate of urinary  $NH_4^+$  by measuring  $Na^+$ ,  $K^+$ , and  $Cl^-$  concentration in a random urine specimen and calculating the urinary anion gap (UAG, mEq/L):

$$UAG = [Na^+] + [K^+] - [Cl^-]$$

On a typical diet,  $Cl^-$  is the main anion accompanying urinary  $NH_4^+$ , and the concentration of  $Cl^-$  exceeds the sum of the concentrations of  $Na^+$  and  $K^+$ . Because urinary  $NH_4^+$  is not directly measured, the UAG is a negative quantity or close to zero in healthy individuals. In the instance of regeneration-defect RTA the rate of  $NH_4^+$  excretion is low, and the rate of  $Cl^-$  excretion is accordingly also low and its concentration is usually

**Figure 322-5** This decision tree presumes that nonrenal causes of hyperchloremic metabolic acidosis, such as viral gastroenteritis, have been ruled out. The usual presentation of RTA is either failure to thrive during infancy or growth progress delay in early childhood. This pathway of decision points is intended for the initial evaluation by a primary care provider and is not complete and does not list all the possibilities. After confirming a low rate of  $\text{NH}_4^+$  excretion, the algorithm depicted has two main branch points based on the serum potassium concentration. If the serum  $\text{K}^+$  is low or normal and a Fanconi syndrome is not found, the pathway then branches between either an isolated  $\text{HCO}_3^-$  reclamation defect or a  $\text{HCO}_3^-$  regeneration defect. Monogenic causes of an isolated reclamation defect (if a Fanconi syndrome is excluded) are rare. An isolated reclamation defect is more likely to be encountered as a duration-limited defect in low-birth-weight infants with delayed maturity of tubular function. Beyond this decision point, referral to a pediatric kidney disease specialist is appropriate. If hyperkalemia is found and a  $\text{K}^+$  secretory defect confirmed by TTKG, possibilities include PHA type 1, salt-losing CAH, and PHA type 2 and referral to a pediatric kidney disease specialist or endocrinologist is appropriate. CAH, congenital adrenal hyperplasia; PHA, pseudohypoaldosteronism; RTA, renal tubular acidosis; TTKG, transtubular potassium gradient;  $(U - B) \text{PCO}_2$ , urine minus blood  $\text{PCO}_2$ .

less than the sum  $[\text{Na}^+] + [\text{K}^+]$ , in the formula above. In this instance, the UAG is positive. This estimate is less reliable if urine pH is relatively alkaline, exceeding 6.7, at which  $\text{HCO}_3^-$  becomes a significant component of the unmeasured anions. For example, at a urine pH of 7.0 the concentration of  $\text{HCO}_3^-$  in urine is approximately 10 mEq/L; at a pH of 7.3, it is approximately 20 mEq/L. The UAG is normal in reclamation-defect RTA during the acidemia that ensues after stopping alkali treatment. The UAG estimate in such patients is not reliable during alkali treatment because of massive  $\text{HCO}_3^-$  wasting. The reliability of this estimate is also negatively affected by an increase in other unmeasured anions, such as ketoacid anions or sulfate (the latter may be a consequence of a high protein intake).

Another surrogate measure for urinary  $\text{NH}_4^+$  is the urine osmolal gap (UOG, mOsm/kg; osmolality is expressed as mOsm per kg of water), estimated from urinary constituents as:

$$\text{UOG} = [\text{measured urine Osm}] - (2[\text{Na}_u + \text{K}_u] + [\text{urea}_u] + [\text{glucose}_u])$$

During the first several weeks of life, an infant receiving formula simulating breast milk has a protein intake nearly aligned with the rate of synthesis of new protein, and the “acidogenic drive” is at a low set point. In this setting the mechanism for an adaptive upregulation of  $\text{NH}_4^+$  production has not been fully activated and the urine anion gap may be positive and incorrectly interpreted as consistent with RTA, even in a

normal infant. The concentration of urea in urine ( $[\text{urea}]_u$  as (mM/L) in the above equation), is calculated as  $\text{urea}_u = (\text{urea nitrogen in urine [mg/dL]}/2.8)$ . If glucosuria is not present then  $[\text{glucose}]_u$  is zero. However, if glucosuria is present (Fanconi syndrome) and glucose is reported in units of mg/dL, then  $[\text{glucose}]_u$ , mM/L = (glucose in urine, mg/dL/18). A UOG of more than 100 mOsm/kg suggests that urinary  $\text{NH}_4^+$  excretion is not impaired and that the unmeasured  $\text{NH}_4^+$  is a significant component of the osmolal gap. The actual  $\text{NH}_4^+$  is about one-half of the UOG because the concentrations of  $\text{NH}_4^+$  and  $\text{Cl}^-$  are approximately equal. One caveat is that a child with possible reclamation-defect RTA who has not begun treatment for acidosis will have appropriate excretion of  $\text{NH}_4^+$  and  $\text{Cl}^-$ . This will be reflected in a normal UOG.

If the serum  $\text{K}^+$  is low or normal, then the diagnostic possibilities include either a reclamation-defect RTA or a nonhyperkalemic-regeneration-defect RTA (see algorithm in Figure 322-5). If urine glucose is positive, then further testing is performed to establish the presence of a Fanconi syndrome in association with the reclamation defect. Empiric treatment with a citrate solution may confirm the diagnosis of a reclamation defect if the dose required for correcting the serum  $\text{HCO}_3^-$  approaches 10 to 15 mEq/kg/day, well above the endogenous rate of acid production. However, an increased dose requirement may also occur in some infants with the rare hybrid-type RTA as a transient phenomenon during the first few years of life.

Ammonium chloride challenge to assess the ability to maximally acidify urine is rarely performed in children. As indicated in Table 322-4, the (U – B)  $\text{PCO}_2$  difference may indicate a limitation of acidification if the (U – B)  $\text{PCO}_2$  is less than 20 mmHg, consistent with a defect of the apical  $\text{H}^+$ -ATPase of the type A intercalated cell. This assessment is only applicable for regeneration-defect RTA and should only be performed after treatment with alkali has restored plasma  $\text{HCO}_3^-$  to normal. However, it is best done under the supervision of a nephrologist in collaboration with a laboratory able to process urine collected with minimal exposure to room air to prevent loss of  $\text{CO}_2$ . Acidification may also be assessed by giving a challenge dose of furosemide, 1 or 2 mg/kg, following administration of a priming dose of fludrocortisone (0.1 mg) several hours earlier. Intact acidification is indicated by a urine pH <5.5.

The presence of medullary nephrocalcinosis on ultrasound examination is consistent with the diagnosis of nonhyperkalemic regeneration-defect RTA, because this type is also associated with hypercalciuria and hypocitraturia. In young infants, obtaining a reliable 24-hour urine collection for the estimation of calcium excretion is not possible without an indwelling catheter. One recourse to avoid an indwelling catheter is to collect multiple random “bag” specimens throughout the day for estimation of the urine calcium-to-creatinine ratio. However, this is only a rough approximation of calcium excretion. The norms for calcium-to-creatinine ratio of a random urine specimen vary with age (see Table 322-5).

If the serum  $\text{K}^+$  is high, suggesting the diagnosis of hyperkalemic regeneration-defect RTA, then the

**Table 322-5**

1–2	1.5	0.56
2–3	1.4	0.50
3–5	1.1	0.41
5–7	0.8	0.30
7–10	0.7	0.25

From Matos V, van Melle G, Boulat O, et al. Urinary phosphate/creatinine, calcium/creatinine, and magnesium/creatinine ratios in a healthy pediatric population. *J Pediatr*. 1997;131:252–257. Copyright © 1997, Elsevier, with permission.

impaired capacity to secrete  $\text{K}^+$  may be confirmed by the measurement of  $\text{K}^+$  and osmolality in plasma and a random urine specimen obtained at the same time that the blood is sampled. The results are used to calculate the transtubular potassium gradient (TTKG):

$$\frac{[\text{K}^+]_u/[\text{K}^+]_p}{[\text{Osm}]_u/[\text{Osm}]_p}$$

Potassium concentration (mEq/L) and osmolality (mOsm/kg) are measured in both urine and plasma and TTKG calculated according to the above equation. Filtered  $\text{K}^+$  is completely reabsorbed proximal to the collecting duct. Urinary  $\text{K}^+$  is essentially all derived from secretion in the distal nephron. The TTKG is a snapshot of the extent to which secretion of  $\text{K}^+$  in the outer collecting duct has established an aldosterone-driven  $\text{K}^+$  gradient between lumen and plasma, before the tubular fluid is further concentrated in the inner medulla of the collecting duct. The actual transtubular gradient in the collecting duct,  $[\text{K}^+]_u/[\text{K}^+]_p$ , is obscured when urine is further concentrated, and this is accounted for by the ratio,  $[\text{Osm}]_u/[\text{Osm}]_p$ , in the denominator. This assessment is not reliable if urine is dilute and  $[\text{Osm}]_u/[\text{Osm}]_p$  is less than 1. In the setting of hyperkalemia, the TTKG should be at least 8 if the collecting duct is responsive to mineralocorticoid. A value less than 8 suggests either insufficient production of aldosterone or a lack of responsiveness of the MR to aldosterone.

The diagnosis of PHA type 1 is suggested by an increased level of plasma aldosterone (see algorithm in Figure 322-5). If aldosterone and plasma renin are suppressed and blood pressure is increased, the rare familial hyperkalemic hypertension syndrome (PHA type 2) is a possibility. If blood pressure is normal or low and aldosterone is low in a clinical setting of salt-wasting, consideration should include congenital adrenal hyperplasia or if aldosterone is high, then the severe, potentially lethal neonatal presentation of PHA type 1 should be considered. If salt-losing congenital adrenal hyperplasia is suspected, initial testing should include plasma cortisol, aldosterone, and 17-hydroxyprogesterone. The salt-losing tendency is

ameliorated by fludrocortisone in conjunction with cortisol replacement. The metabolic acidosis is usually not severe, and further management of congenital adrenal hyperplasia is best done by a pediatric endocrinologist.

## TREATMENT

The aims of treatment are to correct metabolic acidosis and growth impairment, mitigate nephrocalcinosis or bone mineral loss, and in the instance of a primary  $H^+$  secretory defect (regeneration defect), prevent chronic kidney disease caused by progression of nephrocalcinosis. Appropriate treatment with alkali restores growth to its expected trajectory, but the dose required to sustain growth is 2- to 5-fold greater than the expected rate of endogenous acid production. Alkali in this context refers to sodium bicarbonate or a bicarbonate precursor, such as sodium or potassium citrate.

The mainstay of treatment in most children is a citrate solution. Because hypokalemia and  $K^+$  depletion are characteristic of nonhyperkalemic regeneration-defect RTA, a potassium citrate preparation is optimal. The usual liquid preparation contains 2 mEq/mL of  $K^+$  and 2 mEq/mL of  $HCO_3^-$  precursor as citrate. It also contains citric acid to make it palatable. The solution has a pH of approximately 5 before further dilution. The solution is hyperosmolar and must first be diluted 4- or 5-fold with water or infant formula before oral administration. Citrate is a substrate in the citric acid cycle, and its further oxidative metabolism ultimately yields  $HCO_3^-$  in a molar ratio of 2  $HCO_3^-$  for each citrate transported into a mitochondrion. Potassium citrate is also available for older children as a capsule in 2 dose forms, providing either 5 mEq or 10 mEq of  $K^+$ . Because it is slowly released from a wax matrix, the capsule must be swallowed whole and not opened, chewed, or crushed. It is not suitable for young children.

A combined sodium- and potassium citrate solution provides 1 mEq/mL of  $Na^+$  and  $K^+$  and also requires dilution before administration. However, potassium-containing solutions must be avoided in hyperkalemic forms of RTA. Serum potassium should be monitored, especially if glomerular filtration rate is reduced or if the patient is receiving an angiotensin converting enzyme inhibitor or an angiotensin-receptor blocker.

Sodium citrate solutions (1 mEq/mL) may be used for buffer repletion in the hyperkalemic subtype of regeneration-defect RTA. These solutions provide 1 mEq/mL of  $Na^+$  and thus has a lower osmolality than sodium- and potassium citrate solution (2 mEq/mL) or potassium citrate solution (2 mEq/mL), but it still requires dilution to a lower strength for safety and palatability. Accompanying the multiple transport defects of the Fanconi syndrome, sodium-coupled absorption of filtered citrate by the NDC1 transporter is also decreased. The consequent enhanced urinary citrate excretion provides protection against the development of nephrocalcinosis and nephrolithiasis in reclamation-defect RTA with Fanconi syndrome.

The total daily dose requirement of citrate should be divided into 3 or 4 doses so as to minimize the amplitude of fluctuations of the serum  $HCO_3^-$  level that may occur with less frequent administration. In view of data suggesting that metabolic acidosis inhibits growth hormone secretion, administration of a somewhat larger dose of a citrate solution at bedtime to coincide with the nocturnal peak of growth hormone release has been advocated.

Citrate accomplishes 2 aims of treatment: inhibition of stone formation by complexing ionic calcium in urine and, as a bicarbonate precursor, correction of metabolic acidosis. However, citrate administration can also raise the risk of calcium phosphate stone formation as the urine becomes even more alkaline in individuals with hypercalciuria. This may be monitored by periodic assessment of the supersaturation index of calcium phosphate. This assessment is available at clinical laboratories specializing in kidney stone disease management (see Tools for Practice section). The exact mechanism whereby oral administration of citrate increases urinary citrate is not known. There are data suggesting that a pH sensor in the proximal tubule cell may detect an increase in intracellular pH and downregulates tubular absorption of filtered citrate.

Oral ingestion of  $NaHCO_3$  may also be used, but the rapid buildup of  $CO_2$  in the stomach after ingestion may cause gastric distention. However, this approach may be a preferable means of buffer repletion in infants who refuse citrate solutions. A quarter teaspoon of baking soda powder ( $NaHCO_3$ ) provides 13 mEq each of  $Na^+$  and  $HCO_3^-$  and should be diluted in water or infant formula. Tablets of  $NaHCO_3$  are also available and may be crushed.

Adequate treatment of nonhyperkalemic RTA with citrate should lessen hypercalciuria. However, nephrocalcinosis, once established, is generally not reversible. The aim of treatment is to prevent its further progression to chronic or end-stage kidney disease. Correction of acidosis in patients with regeneration-defect RTA does not ameliorate the hearing impairment associated with the 2 autosomal-recessive forms of proton pump defects (see Table 322-3).

A dietary intake emphasizing meat is acidogenic, thus, a dietician may help with more appropriate meal planning. Intake of fruits and vegetables should be encouraged, because some of these food items are also sources of both potassium and citrate. Orange juice prepared from concentrate is more effective than lemonade as a source of citrate. Lemon or lime juice squeezed from fruit or prepared from concentrate has been shown to provide more citrate, but less potassium, than orange juice or lemonade. Natural lemon juice is more effective than lemonade as a source of citrate.

Growth and serum electrolytes should be monitored periodically. The serum  $HCO_3^-$  should be maintained near the upper limit of the range between 25 and 30 mEq/L (blood should be drawn just before the next dose of alkali). At these levels of  $HCO_3^-$ , osteoclastic bone resorption may be suppressed sufficiently to lower the risk of osteopenia or osteoporosis over the long term.

## ROLE OF THE PRIMARY CARE PHYSICIAN

The RTAs are complex disorders that commonly present as failure to thrive. There are many causes of failure to thrive. An assessment of growth should include previous height and weight data, thyroid function, and bone age. A correct diagnosis of RTA must be made early in life and appropriate treatment initiated to promote growth and mitigate bone mineral loss and nephrocalcinosis. The role of the primary care physician is to be aware of the possibility of RTA and to take some initial steps in the patient's workup, such as calculation of the UAG or UOG. More detailed studies and explanations of this complex disorder to parents are best accomplished by a pediatric kidney disease specialist. Moreover, genetic counseling is needed for parents with a child affected with a monogenic RTA disorder in anticipation of possible future pregnancies. Commercially available gene testing is available for some of the implicated genes (see Tools for Practice section for a link listing laboratories for genetic testing) and is best done in conjunction with genetic counseling. The hereditary forms of RTA are rarely encountered in primary care practice. As discussed above, identified mutations, including the 11 listed in Table 322-3, probably account for only a subset of instances of RTA. There are other candidate genes which may be affected but have not yet been identified. The possibility of a sporadic nongenetic occurrence of RTA, perhaps because of a medication (see Table 322-2), should be considered.

Once a child is established on an effective treatment regimen and is clinically stable with good growth progress, periodic follow-up by the primary care physician may be done in collaboration with a nephrologist.

Most children with RTA, and especially those with nephrocalcinosis, have an impairment of the urinary concentrating mechanism and a consequent obligatory polyuria. A superimposed dehydrating illness such as diarrhea or protracted vomiting can culminate in profound hypovolemia. This susceptibility may warrant prompt hospitalization and fluid administration before signs of severe dehydration emerge. The susceptibility to hypokalemia in children with regeneration-defect RTA calls for regular monitoring of the serum  $K^+$  and, if it is found to be low, an increase in the dose of the potassium-containing citrate solution should be prescribed. If profound hypokalemia exists with a serum  $K^+$  less than 2.5 mEq/L accompanied by muscle weakness, then prompt hospitalization may be needed. A newborn with a salt-losing tendency, such as is common in severely affected infants with type 1 PHA, may not be diagnosed before discharge from the nursery. The emergence of vomiting, feeding difficulty, listlessness, hypotonia, hyperventilation, pallor, and signs of dehydration call for urgent readmission and vigorous volume and sodium repletion. In the absence of virilization, the presence of congenital adrenal hyperplasia in a male infant may not be recognized at birth and an infant may be discharged from the nursery only to develop profound salt wasting and hypovolemic shock 1 to 2 weeks later. Newborn screening in the United States now includes congenital adrenal hyperplasia.

If compliance with the medication regimen or an intercurrent illness interferes with taking medication, then hospitalization may be needed for parenteral administration of fluid and  $HCO_3^-$  for the treatment of severe metabolic acidosis.

A child with nonhyperkalemic regeneration-defect RTA may experience severe pain during passage of a kidney stone and require hospitalization. If the stone is impacted in a ureter, then monitoring for the development of obstructive hydronephrosis and medical pain management will be needed along with urologic consultation.

### WHEN TO REFER

- RTA is suspected by assessment of UAG or UOG or suggested by family history.
- Fanconi syndrome is suspected.

### WHEN TO ADMIT

- Hypovolemia (often caused by an illness accompanied by diarrhea or vomiting)
- Hypokalemia with a serum  $K^+$  less than 2.5 mEq/L, especially if accompanied by muscle weakness
- If adherence to the medication regimen or an intercurrent illness interferes with taking medication, then hospitalization may be needed for parenteral administration of  $HCO_3^-$  for the treatment of severe metabolic acidosis or parenteral potassium administration for severe hypokalemia
- Kidney stone

## Chapter 323

# RHEUMATIC FEVER

Welton M. Gersony, MD; Thomas J. Starc, MD, MPH

## INTRODUCTION

Acute rheumatic fever is a systemic connective tissue disorder that is characterized by polyarthritis, carditis, and chorea, either singly or in combination. The major long-term consequence is the potential for inflammatory cardiac valvar involvement, leading to chronic heart disease. The other manifestations are self-limiting with no late sequelae. Arthritis clears without joint dysfunction or deformity, and chorea leaves no neuromuscular impediment. Preventing recurrent attacks that carry the risk of recrudescence heart involvement and further cardiac damage is the most important concern.

The major goal of pediatric care is preventing an initial attack of rheumatic fever, which can be accomplished by effective treatment of group A  $\beta$ -hemolytic streptococcal (GAS) pharyngitis. A recent American Heart Association Statement has reiterated that penicillin (either oral penicillin V or injectable benzathene penicillin) remains the treatment of choice. GAS resistance to penicillin has not been documented. For patients who are penicillin-allergic, a number of orally administered antibiotic agents are available.

## EPIDEMIOLOGIC FEATURES

### Incidence

An immunologic reaction to GAS infection is the established cause of rheumatic fever. The incidence of rheumatic fever observed in epidemics of streptococcal pharyngitis is approximately 2% to 3%, whereas the attack rate after sporadic streptococcal upper respiratory tract infection is only approximately 0.2% to 0.3%. In patients who have already had one or more attacks of rheumatic fever, however, the recurrence rate of carditis increases to approximately 15% after subsequent streptococcal infection.

### Age

Rheumatic fever is predominantly a disease of school-aged children, with most first occurrences between 5 and 15 years of age. It is uncommon in children younger than 5 years and extremely rare in children younger than 3 years. When occurring in infancy, acute rheumatic fever is usually associated with severe carditis and congestive heart failure. Polyarthritis caused by rheumatic fever is unusual in the preschool-aged group; rheumatoid arthritis and other inflammatory diseases of the joint are more likely diagnoses. Chorea also is uncommon in early childhood; most of the cases occur in children older than 8 years.

### Host Susceptibility

Rheumatic fever has often been called a *social status disease*, and most studies have noted its strong association with poverty. The major social risk factors that

predispose children to rheumatic fever seem to be crowding and lack of medical attention. Crowding increases the likelihood of transmission of the GAS from person to person, and lack of medical care precludes timely treatment of streptococcal pharyngitis, resulting in the later presentation of a child with signs and symptoms of acute rheumatic fever.

The tendency for rheumatic fever to occur in more than one family member has long been recognized. The observation is noted even when family members are not concurrently living in the same household, indicating that environmental influences are probably not solely responsible for the disease. No genetic factors have been clearly established.

Sex predisposition does not exist in the incidence of arthritis or carditis in childhood, although chorea has been noted to be more common in girls. Sex differences exist, however, in the type of valvular lesions that develop with carditis; boys have a higher incidence than girls of aortic regurgitation. In young adults, mitral stenosis is more common in women than in men.

Numerous primary prevention community programs have demonstrated the efficacy of identifying streptococcal infection by performing throat cultures on susceptible children and treating them early. Furthermore, the widespread application of secondary prevention in the form of antistreptococcal prophylaxis programs for patients after their first attack has significantly reduced the recurrence rate and the additive effects of repeated bouts of carditis.

The incidence of acute rheumatic fever has declined in the last 5 decades in the United States and Europe. However, in economically underdeveloped countries, rheumatic fever remains a common illness in childhood. Continued immigration from the Caribbean Islands, South America, and Southeast Asia is also a factor in the prevalence of the disease in the United States. An apparent resurgence of acute rheumatic fever in certain areas of the United States, both urban and suburban, was reported between 1984 and 1988 and again in 1997 and 1998, but no evidence indicates that this trend has continued. Although the disease persists, the annual incidence may be so low, even at large teaching medical centers, that during 3 years of pediatric training, a resident physician may see very few children with acute rheumatic fever.

## DIAGNOSIS

### Jones Criteria

No pathognomonic clinical findings or specific laboratory tests are available to confirm the diagnosis of rheumatic fever; hence the diagnosis must be somewhat arbitrary and empirical. A list of major and minor criteria for the evaluation and diagnosis of rheumatic fever and rheumatic heart disease was published more than 70 years ago by Dr T. Duckett Jones. These guidelines have been accepted as diagnostic criteria throughout the world and have been modified (1955) and revised (1984) by specifically appointed committees of the American Heart Association. A further revision of the Jones criteria was designated in a 1992 update and was reviewed in 2002. The most

recent revision of the Jones criteria was published in 2015. The major highlights include proposing different criteria for medium-risk and high-risk versus low-risk populations, the use of Doppler echocardiography in the diagnosis of silent carditis, and including monoarticular arthritis as a major criterion in moderate-risk and high-risk populations. Low risk is defined as having an incidence of acute rheumatic fever of fewer than 2 per 100,000 school-aged children per year or an all-age prevalence of rheumatic heart disease of 1 or fewer per 1,000 population per year. These guidelines are given in Table 323-1. The 5 major manifestations in order of decreasing frequency are polyarthritis, carditis, chorea, erythema marginatum, and subcutaneous nodules. The 2 major manifestations involving the skin, especially the nodules that were most often seen only after multiple attacks of rheumatic fever, have been extremely uncommon in the United States in recent years.

Poststreptococcal reactive arthritis (PSRA) may complicate the diagnosis of acute rheumatic fever. PSRA refers to patients who have arthritis following GAS pharyngitis without other criteria for rheumatic

fever. It remains unclear whether PSRA is a distinct syndrome, or if antibiotic prophylaxis is required.

Minor manifestations of rheumatic fever include elevated acute phase reactants (erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and electrocardiographic (ECG) evidence of prolongation of the PR interval. The clinical observation of fever may be present early in the course of polyarthritis or carditis. Arthralgia is nonspecific and may affect any joint without objective signs of inflammation; it should not be considered a minor manifestation if arthritis is counted as a major manifestation.

Under the current guidelines, the laboratory confirmation of a recent streptococcal infection should be part of the diagnostic evaluation. The absence of evidence of streptococcal infection should make the physician suspicious of the diagnosis of rheumatic fever except in cases in which indolent carditis or chorea are the major manifestations. The tendency to label any low-grade febrile illness with arthralgia for which no obvious cause can be found as rheumatic fever should be avoided.

The Jones criteria should be viewed as a guide to a probable diagnosis of rheumatic fever, but the final diagnosis must remain a clinical judgment. The institution of prophylactic regimens requires prolonged administration of antistreptococcal agents, which places an important responsibility on the physician who diagnoses rheumatic fever. A false diagnosis of acute rheumatic fever results in unnecessary long-term antibiotic prophylaxis and should be avoided. Hospitalizing a child who has arthritis or carditis may be advisable for observation, appropriate documentation of a poststreptococcal illness, and initiation of treatment. Hospitalization also emphasizes to the parents the seriousness of the disease and the importance of prophylaxis to prevent recurrence. Because of the specific association of Sydenham chorea with rheumatic fever, hospitalizing a child who has this manifestation should not be mandatory if abnormal neuromuscular activity is mild and unlikely to cause self-inflicted injury.

Major Clinical Manifestations

The sequence of the manifestations of rheumatic fever is noteworthy: polyarthritis, when it occurs, is usually present before the onset of carditis. Although carditis may be present without preceding joint symptoms, most often the apical systolic murmur of mitral valvulitis occurs within 2 weeks of the onset of arthritis. The diastolic murmur of aortic valvulitis takes longer to appear and may not be heard for 6 to 8 weeks after the joint signs and symptoms appear. Chorea may develop during the convalescent phase of carditis, although a longer latent period usually occurs. Classically, chorea appears as an independent manifestation of rheumatic fever long after the initial streptococcal infection. Most cases begin 2 months after streptococcal infection, with episodes still occurring up to 6 months afterward. Although chorea and carditis may coexist, chorea and polyarthritis rarely appear concurrently, presumably because of the difference in the latent periods.

Polyarthritis

Polyarthritis is the most common initial manifestation of rheumatic fever, and usually involves the large

ARF, acute rheumatic fever; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; GAS, group A streptococcal infection. From Gewitz MH, Baltimore RS, Tani LY, et al. Revision of the Jones Criteria for diagnosis of acute rheumatic fever in the era of Doppler echocardiography. A Scientific Statement from the American Heart Association. *Circulation*. 2015;131(20):1806–1818. Copyright © 2015 American Heart Association. Reprinted by permission.

joints of the lower extremities, particularly the ankles or knees. Polyarthritis may result in the complaint of joint pain while walking and is often initially considered to be secondary to trauma. Other large joints (for example, wrists or elbows) become involved in a migratory fashion. An affected joint characteristically is warm and reddened but minimally swollen. Involved joints are exquisitely sensitive to touch and painful on motion. Arthralgias, or aching in the joints without objective signs of inflammation, are suggestive of but not specific for rheumatic fever. The 2015 modification of the Jones Criteria recognizes that only in moderate-risk or high-risk populations, monoarthritis and polyarthralgia may be counted as a major criteria and monoarthralgia may be counted as a minor criteria of rheumatic fever. Fever is almost always present.

### Carditis

The inflammation of cardiac tissue is characteristically expressed as valvulitis, but pancarditis involving the myocardium and pericardium may be present in severe cases. The murmurs audible in rheumatic carditis are the result of mitral or aortic valvulitis, or both, with mitral involvement by far the most common. The auscultatory diagnosis of valvulitis often includes the presence of an apical mid-diastolic murmur. Pericarditis typically is silent, but a friction rub and distant heart sounds may occasionally be noted. Isolated pericarditis without associated auscultatory findings of mitral or aortic involvement, however, is not consistent with the diagnosis of acute rheumatic fever. Although viral inflammation of the heart by coxsackievirus type B or Kawasaki disease may be associated with myocarditis and pericarditis, these entities do not cause clinically evident valvulitis. The recent AHA Revised Jones criteria now also include subclinical carditis, which is defined as the presence of definite Doppler and echocardiographic valvular changes in the absence of clinical auscultatory findings.

Clinical carditis, diagnosed by the presence of valvulitis with characteristic murmurs, may be conveniently designated as mild, moderate, or severe. Such a categorization is useful in the approach to management and to establishing a prognosis for developing rheumatic heart disease. The results of the auscultation of the heart and evaluation of murmurs are influenced by fever and tachycardia; therefore, the patient should be re-examined frequently after the diagnosis of acute rheumatic fever and after the temperature has normalized with aspirin therapy. A changing functional murmur in an anxious or febrile child does not indicate the presence of carditis.

**MILD CARDITIS.** Mild carditis is characteristically defined by the presence of a prominent, high-pitched, apical systolic murmur typical of mitral insufficiency. The heart murmur of mild carditis is usually of grade 2 to 3 (on a scale of 1–6) intensity and occupies all or most of the systole. A mid-diastolic rumble at the apex is not present. The heart size on chest radiograph is usually normal.

**MODERATE CARDITIS.** Moderate carditis is defined as both long systolic and prominent mid-diastolic

apical murmurs, reflecting a greater severity of mitral valvulitis, a basilar diastolic murmur of aortic valvulitis, or a combination of mitral and aortic valvulitis. An aortic diastolic murmur, which is high pitched and decrescendo in character, is usually heard best during end expiration, with the diaphragm of the stethoscope firmly held at the third left intercostal space. A chest radiograph may show mild cardiac enlargement.

**SEVERE CARDITIS.** Severe carditis is defined by the presence of either pericarditis or congestive heart failure in addition to mitral or aortic valvulitis. The quality of the heart sounds may be poor because of either pericardial effusion or low cardiac output. Murmurs may become more intense as cardiac compensation improves. The chest radiograph shows obvious cardiomegaly, and may reveal pulmonary vascular congestion compatible with left-sided heart failure and pulmonary edema; an appearance also may be consistent with what is referred to as *rheumatic pneumonia*.

**SUBCLINICAL CARDITIS.** The 2015 AHA revision of the Jones criteria includes a new category of heart disease in patients who have no clinical evidence of carditis. New recommendations suggest that echocardiography and Doppler testing should be performed in any patient suspected of having rheumatic fever, even in the absence of clinical findings of cardiac disease. Strict echo/Doppler criteria should be followed in order to make the diagnosis of active subclinical carditis, which includes changes in the mitral or aortic valve and documented pathologic mitral or aortic regurgitation. Studies suggest that the prevalence of subclinical carditis in patients with no clinical signs of cardiac involvement is significant. In a meta-analysis of 23 studies, the weighted pooled prevalence of subclinical carditis was 16.8% (95% confidence interval: 11.9%–21.6%). The weighted pooled persistence of carditis 3 to 23 months after diagnosis was 44.7% (95% confidence interval: 19.3%–70.2%) from 11 articles.

**IMAGING.** For the documentation and quantification of pericardial effusion, 2-dimensional echocardiography is invaluable, and it confirms the diagnosis and severity of valvar involvement. The finding of minimal valvular regurgitation by Doppler ultrasound, however, should not constitute the basis of a diagnosis of carditis. Doppler studies in healthy individuals often show a small degree of regurgitation across the mitral valve; trivial aortic valve regurgitation also is described in well children. Strict Doppler and echocardiographic criteria are available in the most recent AHA guidelines to differentiate valvular disease typical of rheumatic carditis from normal variants. The long-term effects of a false diagnosis of acute rheumatic fever with the requirements for chronic antibiotic therapy and potential lifestyle and psychological effects should not be underestimated. There are a number of recent studies using 2-dimensional echocardiography as a screening tool to identify children with a past history of unsuspected rheumatic carditis. It is important to distinguish the use of echocardiography in areas with a high incidence of endemic rheumatic fever from its use in the diagnosis and management of acute rheumatic fever in areas of low incidence.

### Chorea

The clinical picture of Sydenham chorea includes that of poor neuromuscular coordination, sometimes first detected by a change or sloppiness in handwriting. A wide variety of jerky, involuntary movements may occur for 6 to 8 weeks when most cases of chorea are active. Neurologic examination may give evidence of specific deficiencies, particularly in trunk and upper extremity control of movements. A protective environment is recommended while the process is active. Occasionally, mild sedation is indicated, and agents such as valproic acid or prednisone may help in the treatment of more severe movement disorders.

When chorea occurs as an isolated manifestation, the patient is usually afebrile and the sedimentation rate is normal. Because of the long interval after the initiating streptococcal infection, the antistreptolysin O (ASLO) titer is typically normal or only mildly elevated. A murmur of mild mitral insufficiency may be noted.

### Erythema Marginatum

Erythema marginatum is a transient pink rash that has irregular, deeper-colored serpiginous borders that may be seen on the smooth, hairless surfaces of the inner aspect of the upper arms and thighs or trunk. This manifestation, although a specific finding for acute rheumatic fever, has been encountered infrequently in recent decades.

### Subcutaneous Nodules

Subcutaneous nodules are characteristically pea-sized and are usually located on extensor surfaces of fingers, toes, elbows, and other joints and less often on the occiput. They usually reflect a longstanding or smoldering illness after severe carditis; nodules may persist for weeks or months. Subcutaneous nodules are rarely found in children with rheumatic fever in the present era.

### Minor Clinical Manifestations

Among the minor criteria, fever, although almost always present, is nonspecific, as is arthralgia. An elevated acute-phase reactant, such as the ESR, is an invaluable though nonspecific laboratory sign of inflammation in children with acute rheumatic fever. Initial values usually range from 60 to 120 mm/hour. However, in patients with chorea the sedimentation rate is normal because of the long interval beyond the antecedent streptococcal infection. Elevated CRP, although helpful in diagnosing cases with borderline findings, also occurs in a variety of other diseases.

Prolongation of the PR interval (first-degree heart block) on ECG is considered to be a vagal effect and supports the diagnosis of rheumatic fever. It is most commonly noted when polyarthritis is apparent and is not necessarily associated with carditis. The ECG is almost always otherwise normal regardless of cardiac involvement. Although PR interval prolongation is the common manifestation, second- or third-degree heart block occasionally occurs, indicating a further heightening of vagal tone, perhaps more pronounced in the rheumatic state than in other acute illnesses. It is important to note that a first- or second-degree heart block is not a major criterion for carditis, a harbinger

of potential rheumatic heart disease, a threat to progress to complete heart block, nor a cause of symptoms.

The minor criteria have also been modified to differentiate low-risk versus moderate-risk and high-risk populations. Minor criteria in the low-risk group include polyarthralgia, fever higher than 38.5°C (101.3°F) and ESR above 60 mm/hr. In contrast, the moderate-risk and high-risk group minor criteria have been changed to include monoarthralgia, fever above 38°C (100.4°F), and ESR above 30 mm/hr. CRP above 3.0 mg/L and a prolonged PR interval remain the same in both groups.

Streptococcal pharyngitis presumptively precedes an attack of rheumatic fever, even though some patients fail to report such a history. Scarlet fever occasionally is followed by signs of polyarthritis or carditis, but suppurative streptococcal disease, such as a skin infection, is not a precursor of rheumatic fever. Throat cultures may be misleading in the evaluation of patients suspected of having rheumatic fever because the streptococcal infection antedates the common manifestations of polyarthritis and carditis by periods varying from 3 to 8 weeks; only 50% or fewer of patients who have rheumatic fever continue to harbor streptococci during the course of their illness.

The most reliable evidence of a preceding streptococcal infection is obtained by demonstration of an antibody response to one or more of the streptococcal antigens. The most common of these, the ASLO titer, reaches maximal levels 3 to 5 weeks after infection and gradually declines to preinfection levels 6 to 12 months later. The ASLO titer is elevated in approximately 85% of patients who have rheumatic fever; titers are never extremely low. Serologic evidence of an antecedent streptococcal infection rises to 95% if other streptococcal antibody tests (eg, antihyaluronidase, antideoxyribonuclease B, antistreptokinase) are performed.

The temporal relationship between the onset of the common manifestations of rheumatic fever and the antecedent streptococcal infection is illustrated in Figure 323-1. As shown, polyarthritis and carditis

**Figure 323-1** The relationship of the onset of rheumatic manifestations to antecedent streptococcal infection and streptococcal antibody titer (ASLO). (Modified from Stollerman GH. Rheumatic Fever and Streptococcal Infection. New York, NY: Grune & Stratton; 1975.)

usually occur 3 to 5 weeks after infection. The ASLO titer peaks before the onset of the clinical symptoms and then declines gradually. Occasionally, children complain of abdominal pain after a streptococcal infection for which medical or surgical evaluation is sought, and this symptom may occasionally precede signs of joint or cardiac involvement.

## MANAGEMENT

The therapeutic management of acute rheumatic fever includes the use of antistreptococcal antibiotics and anti-inflammatory agents.

### Antistreptococcal Therapy

The eradication of GAS infection (even in the absence of a positive throat culture) by antibiotic treatment is the foremost principle in management of acute rheumatic fever. Antibiotic treatment must always be followed immediately by the institution of a prophylactic program to prevent reinfection (see Recurrence of Rheumatic Fever). Penicillin is the drug of choice prescribed initially in dose and duration to maintain therapeutic blood levels for 10 days. Several treatment schedules, which periodically are revised, are outlined by the American Heart Association. The intramuscular administration of the long-acting repository benzathine penicillin G (Bicillin) is the preferred treatment method at the time of diagnosis, because it ensures therapeutic levels for a sufficient length of time. A single injection of 1.2 million units for children 5 to 15 years of age is recommended. Alternative methods are oral penicillin, 200,000 or 250,000 units (penicillin G or V), given 3 or 4 times a day for a full 10 days; or a combination of oral and intramuscular penicillin.

For patients sensitive to penicillin, erythromycin may be used for antistreptococcal therapy. The sulfonamide drugs, which are bacteriostatic rather than bactericidal, are not effective for streptococcal eradication. They can be used in rheumatic prophylaxis programs to prevent reinfection; however, they are rarely used in the present era.

Following the initial treatment to eradicate streptococci, a program of antibiotic prophylaxis must be instituted. (See Prevention of Recurrence of Rheumatic Fever).

### Anti-inflammatory Therapy

Salicylates are indicated in the presence of acute, painful arthritis during the febrile phase of acute rheumatic fever. The duration of salicylate therapy usually ranges from 4 to 8 weeks. The average initial amount prescribed should be approximately 50 to 75 mg/kg/day given in 4 divided doses, and extremely high doses are not required. Aspirin is used for symptomatic relief only. Aspirin administration is usually associated with a rapid and significant improvement in objective arthritis signs and symptoms and with almost immediate defervescence. Specific blood levels do not need to be reached or maintained if clinical signs have disappeared. No evidence exists that salicylate administration affects the clinical course or later manifestations of cardiac involvement. It should be emphasized that high-dose aspirin may lead to significant side effects, including tinnitus and decreased hearing, gastric

irritation and, hepatotoxicity. Several small studies comparing aspirin and nonsteroidal anti-inflammatory medications have demonstrated similar results in the speed of resolution of arthritis. However, at this time insufficient data exist to routinely recommend the use of nonsteroidal anti-inflammatory agents in the treatment of rheumatic fever.

The administration of steroid hormones, most commonly prednisone, is indicated for severe cardiac involvement characterized by pancarditis with congestive heart failure. When myocarditis seems to be fulminant, steroid therapy has been shown to significantly improve survival; however, as with salicylates, no evidence of long-term palliative effects on chronic rheumatic valvular disease is available. The duration of steroid treatment may be extended to 1 to 3 months in severe cases, with varying schedules of tapering the dose and possibly adding salicylate therapy. As reviewed in a 2012 Cochrane Report, the studies comparing aspirin to steroids in the prevention of long-term cardiac disease have failed to provide evidence of superiority between the 2 methods of treatment.

Additional, specific therapeutic measures to control congestive heart failure may be useful (eg, diuretics, digitalis). Furosemide (Lasix) is used for the management of pulmonary congestion with left-ventricular failure. If digitalis (digoxin) is used, it should be administered cautiously; the threshold for toxicity may be reduced in the presence of inflammatory myocarditis. Withholding digitalis for 1 or 2 days until steroid therapy has begun to suppress the myocarditis may be prudent. Serum potassium levels should be monitored, because steroids and furosemide both decrease body potassium, predisposing the patient to digitalis intoxication. Enalapril is also sometimes used in patients with mitral valve insufficiency.

### Limitation of Activity

The role of bed rest in the treatment of rheumatic fever has been deemphasized in recent years. For children with arthritis, ambulation can be permitted when pain and joint tenderness improve. Patients who have stable, mild cardiac involvement can be allowed to ambulate when they feel well enough. For patients who have more severe carditis, the length of restricted activity is individualized according to the severity of cardiac involvement.

## OUTCOMES OF RHEUMATIC HEART DISEASE

In the months and years that follow an attack of rheumatic fever, the auscultatory findings often change from those heard during the acute episode. The apical systolic murmur of mitral insufficiency heard initially may diminish or even completely disappear. This finding contrasts with the aortic diastolic murmur, which will almost always persist during the follow-up period. An initial diagnosis of carditis does not necessarily imply progression to permanent heart damage. When a child is labeled as having history of acute rheumatic fever, the additional appellation of rheumatic heart disease must be reevaluated continually. Even patients with severe carditis in the acute phase will show

remarkable improvement in the weeks and months after the recuperative period; more than one-half of murmurs of mild or moderate mitral insufficiency will disappear completely. Nevertheless, the ultimate development of rheumatic heart disease after a first attack of rheumatic fever can be correlated with the severity of the acute carditis. In the 10-year follow-up study of treatments begun in 1951, approximately 30% of patients who had mild carditis and 50% of those who had moderate carditis developed chronic rheumatic heart disease (mitral insufficiency or stenosis or aortic regurgitation, or any combination). Nearly 75% of the patients with severe carditis will have residual heart disease.

Most children who develop rheumatic heart disease after a single attack of rheumatic fever have mitral regurgitation. The others either have both mitral and aortic regurgitation or aortic regurgitation alone. Mitral stenosis evolves slowly, usually after repeated episodes of acute rheumatic fever, but it sometimes evolves unexpectedly, many years after initial mild mitral valvulitis, which was perhaps previously undiagnosed. Isolated mitral stenosis is unusual before early adulthood and has become a rare finding in economically developed nations.

An issue that arises in the follow-up of children who have rheumatic heart disease is the amount of physical activity permitted. In general, children who have mild mitral regurgitation with normal heart size should be allowed to engage in all athletic activities, except perhaps for the most strenuous competitive sports. Children who have more severe mitral regurgitation or aortic insufficiency with cardiomegaly should have some restriction of their activities and a continuing appropriate regimen. If symptoms of fatigue or exercise intolerance persist despite medical management, then a full diagnostic evaluation should be performed; if appropriate, surgical intervention with valvuloplasty or valve replacement should be considered.

### Recurrence of Rheumatic Fever

One of the most striking characteristics of rheumatic fever is its tendency to recur. Before the introduction of preventive measures, most patients who had an initial attack of rheumatic fever had one or more recurrences, or what seemed to be a chronic “smoldering” prolongation of a single episode. The recurrence rate is highest during the first 3 years after an initial attack; it diminishes with time after the original episode, and recurrence is rare in adulthood.

The rationale for antibiotic prophylaxis in a patient with known rheumatic fever is protection against recurrence of rheumatic fever through the prevention of GAS infection. To prevent recurrent attacks, continuous antimicrobial prophylaxis should be implemented in all patients who have a history of rheumatic fever, including those who present with chorea. Children who initially had cardiac involvement, but have no evidence of residual heart disease should continue prophylaxis for 10 years or until age 21, whichever is longer. If chronic mitral or aortic valvular disease persists, then prophylaxis should be maintained until

age 40. In children who had no cardiac involvement during the initial attack, prophylaxis can be discontinued after 5 years.

### Prevention of Recurrence of Rheumatic Fever

The most effective method for reducing streptococcal infections and rheumatic fever recurrence is by intramuscular injections of long-acting penicillin (benzathine penicillin G [Bicillin LA], 600,000 units for children weighing 60 lb or less and 1,200,000 units for those weighing more than 60 lb). This preventive regimen is most effective when given every 3 to 4 weeks; with residual cardiac involvement, this approach is recommended for at least a 1- or 2-year period, before initiating oral prophylaxis. An every-3-week regimen is recommended for the first 6 to 12 months. Parenteral therapy is the most effective method of prophylaxis, given that strict adherence to a program of daily oral medication is especially difficult for children and adolescents. Some transient discomfort at the injection site (anterior thigh or buttock) may be relieved by a hot bath on the evening of injection.

Alternative methods of prophylaxis include the oral administration of penicillin V (250 mg twice daily) or sulfadiazine or sulfisoxazole (0.5 g once daily for patients weighing 60 lb or less and 1.0 g once daily for patients more than 60 lb). For the exceptional patient who may be sensitive to both penicillin and sulfisoxazole, daily prophylaxis with another agent may be considered. Successful oral prophylaxis is hard to maintain, and if used, its value and need for compliance should be reinforced constantly by the primary care physician. Because rheumatic fever recurrence is less likely after 2 to 5 years, for patients with chronic rheumatic heart disease, an oral regimen can be substituted for intramuscular penicillin. Oral prophylaxis can be instituted immediately for patients who did not have carditis during the acute attack, because under these circumstances recurrences with carditis are extremely rare.

### Bacterial Endocarditis

Individuals who have a history of rheumatic fever without evidence of significant murmurs on follow-up examination are not susceptible to bacterial endocarditis because they do not have damaged heart valves. Recent guidelines from the AHA report that patients with heart disease are more likely to acquire infective endocarditis from frequent exposure to random bacteremic events associated with daily activities than from bacteremia following dental or surgical procedures. The latest guidelines for preventing infective endocarditis therefore recommend antibiotic prophylaxis for patients with prosthetic cardiac valves, previous infective endocarditis, and certain types of repaired and unrepaired congenital heart diseases. Antibiotic prophylaxis before dental or surgical procedures is no longer recommended for patients with mitral or aortic valve disease following rheumatic fever. However, the maintenance of optimal oral health remains an important aspect of preventive care. The recommendations for preventing recurrent episodes of rheumatic fever have not changed.

### Contraception and Pregnancy

Patients who have severe rheumatic heart disease are at high risk of cardiac complications during pregnancy and delivery. Mitral stenosis has an especially high-risk profile. However, mild rheumatic heart disease is well tolerated during pregnancy. Adolescent girls who have rheumatic heart disease should be counseled in regard to contraceptive methods.

Because of the added cardiovascular burden during pregnancy, thorough obstetrical care should be provided from the first trimester through delivery. Prophylaxis against streptococcal infection should be continued. Psychosocial support may be needed, especially for pregnant teenagers with significant rheumatic heart disease who may face medical complications during pregnancy. If the early termination of a pregnancy is decided upon, therapeutic abortion should be performed in the hospital.

### WHEN TO REFER AND WHEN TO ADMIT

All children with acute rheumatic fever should be hospitalized and referred to a cardiologist for evaluation and management.

### Chapter 324

## RHEUMATOLOGIC DISEASES

David M. Siegel, MD, MPH; Harry L. Gewanter, MD;  
Shashi Sahai, MD

### JUVENILE IDIOPATHIC ARTHRITIS

Juvenile idiopathic arthritis (JIA; previously referred to as *juvenile rheumatoid arthritis* or *juvenile chronic arthritis*) is an uncommon collection of clinical syndromes that share the feature of chronic childhood arthritis. The diagnosis is applied to any child younger than 16 years who has persistent arthritis of 1 or more joints lasting for more than 6 weeks in whom all other diseases have been excluded. JIA is classified further into 7 subtypes, with most patients fitting into systemic-onset, oligoarthritis, or polyarthritis based on the clinical course over the first 6 months of illness.

Although JIA is the most common of the pediatric rheumatic diseases, its true incidence and prevalence are unknown. For all subtypes taken collectively, the peak age at onset is between 2 and 4 years, with a smaller peak later in childhood. Overall, a general female predominance is found, but not in all subtypes. The best estimate of prevalence is approximately 0.5 to 1 case per 1,000 children; thus, approximately 40,000 to 100,000 children in the United States have JIA at any given time.

#### Etiology

The exact cause of JIA is unknown. Data on the frequency of certain subtypes of human leukocyte antigens (HLA) in JIA (eg, HLA-DR5 and -DR8 in younger girls who have oligoarticular JIA, HLA-DR4 in rheumatoid factor [RF]-positive polyarticular JIA, and HLA-B27 in older boys who have enthesitis-related JIA) have led to the concept of a genetic predisposition for the development of an inflammatory arthritis that may be triggered by any of several events, such as trauma, infection, or emotional stress.

Other areas of interesting research include investigations of immunologic abnormalities involving auto-antibodies, cytokines, immunoregulation, and the function of and communication between T and B lymphocytes and antigen-presenting cells. The precise nature of these interactions and how they result in the development of JIA remain to be discovered, but the success of specific cytokine-directed therapy (eg, anti-tumor necrosis factor [TNF], anti-interleukin [IL] 1, anti-IL6 antibodies) supports the central role of these proinflammatory mediators in the clinical manifestations and course of JIA.

#### Rheumatologic Disorders With Arthritis

Juvenile ankylosing spondylitis and the other spondyloarthropathies can present as a subtype of JIA at their onset, especially in an older child who is HLA-B27 positive. Acute rheumatic fever, although long in decline in the United States and other industrialized

nations, has seen a resurgence in the last few decades. Children with acute rheumatic fever can experience both arthralgia and arthritis, classically characterized as migratory. Systemic lupus erythematosus (SLE) has arthritis as one of its major manifestations, but it can be differentiated from JIA by its other systemic features and specific laboratory test abnormalities. As well, children with SLE may have arthralgia without arthritis. Although its sex distribution is equal in younger children, female preponderance is found after puberty. Dermatomyositis is characterized more typically by inflammatory muscle involvement than by arthritis, but children can be affected with joint inflammation and contractures. Scleroderma is occasionally associated with arthritis, but it has classic dermatologic and other manifestations that distinguish it from JIA.

### Clinical Manifestation

Because the diagnosis of JIA is based on clinical findings, the history and physical examination are paramount; no unique or specific diagnostic laboratory tests yet exist. Only by considering all the data on the child's presentation and course is the physician able to diagnose JIA.

The presence of arthritis or inflammation in the joint is an absolute criterion for diagnosing JIA. Arthritis is defined as the presence of intra-articular swelling or effusion or when 2 or more of the following occur: joint pain or tenderness with motion, limitation of joint motion, or increased warmth overlying the joint. Arthralgia (joint pain) is a relatively frequent symptom in children, but true joint inflammation, or arthritis, is much less common. Younger children rarely complain of joint pain but may instead become irritable, stop walking or using an extremity, or regress in their behavior. In fact, a recent retrospective review of presenting complaints at a pediatric rheumatology center found that pain was not a predictor of the diagnosis of juvenile arthritis. Other symptoms include decreased appetite, malaise, inactivity, morning stiffness, nighttime joint pains, and failure to thrive. Features that may also be present in children who have chronic arthritis (varying with the subtype) include fever, rash, lymphadenopathy, hepatosplenomegaly, polyserositis, subcutaneous (rheumatoid) nodules, vasculitis, and growth retardation. The pattern, as well as the number of involved joints, family history, and other factors are important in classifying the disease.

### Systemic-Onset Juvenile Idiopathic Arthritis

Even though the hallmark of systemic-onset JIA (historically referred to as *Still disease*) is its extra-articular manifestations, the eventual presence of arthritis is necessary to confirm the diagnosis. Systemic-onset JIA, which affects approximately 15% of all children who have JIA, is slightly more common among boys than girls and usually begins at an early age, though it has even been recognized in adults (adult-onset *Still disease*). The systemic features may persist for months and occur or recur independently of the arthritis.

Daily intermittent fevers characterize systemic-onset JIA, with rectal temperature reaching as high as

40°C to 41°C (104°F–106°F), most often in the afternoon, and then returning to normal or subnormal levels (known as a *quotidian fever pattern*). An evanescent, salmon-colored rash often accompanies the fevers. The lesions are small macules or papules, frequently with central clearing, and often appear in areas of increased heat (eg, axilla). Mild abrasion of unaffected skin can precipitate the appearance of the rash (Koebner phenomenon).

Polyserositis in the form of pericarditis or pleuritis is common; enlargement of lymph nodes, liver, and spleen may be of sufficient size to suggest the presence of a malignancy. These serosal effusions, however, are rarely symptomatic or clinically significant. Although these children frequently complain of myalgias or arthralgias when they are febrile, they may have few symptoms when the fevers resolve. The arthritis may occur at any time after the onset of disease, and in some patients, it appears only days to weeks after the systemic signs occur. The arthritis tends to be polyarticular, involving both large and small joints, and can be persistent, destructive, and severe.

Laboratory studies reveal a high white blood cell count, with predominance of band forms and polymorphonuclear leukocytes. Most patients are anemic. Thrombocytosis is frequent, as are significant increases of the acute-phase reactants (eg, erythrocyte sedimentation rate [ESR] and C-reactive protein). Rheumatoid factor (RF) and antinuclear antibody (ANA) tests are rarely positive. Serum immunoglobulin and complement levels are usually normal but may be elevated, reflecting the degree of inflammation, and sometimes evidence of a vasculopathy and an intravascular consumption coagulopathy is found. An unusual but severe and potentially fatal complication of systemic-onset JIA is macrophage activation syndrome. This disorder can be rapidly progressive and may be difficult to distinguish from a flare in the underlying disease, but hallmarks are dramatically high ferritin levels (>10,000 ng/mL), paradoxically decreasing ESR accompanied by decreased fibrinogen, increased triglycerides, leucopenia, anemia, thrombocytopenia, and hepatic failure. Definitive diagnosis is based on bone marrow biopsy, and quick therapeutic intervention is necessary.

The clinical course of systemic-onset JIA is extremely variable. Some children have a single systemic episode that lasts weeks to months and have few joint problems; others have multiple systemic episodes before developing the arthritis, which can be oligoarticular, but more commonly is polyarticular in distribution. Poor prognostic signs include the continued presence of systemic features and a platelet count exceeding 600,000/mm<sup>3</sup> 6 months after onset. At least a third of these children will develop severe arthritis.

### Polyarticular Juvenile Idiopathic Arthritis

Approximately 30% to 35% of children who have JIA have the polyarticular type, which can be subdivided into immunoglobulin (Ig) M-RF-positive (approximately 10% of the total) and IgM-RF-negative (approximately 25%) forms. So-called hidden RFs have been found in all subgroups, but their significance remains obscure. Finding a meaningfully positive RF

in a child younger than 7 years is rare. Systemic features in polyarticular JIA are usually mild and include low-grade fever, easy fatigability, and slowing of growth. The growth problems may be local (eg, micrognathia) or generalized and can occur regardless of whether the child receives corticosteroid treatment. Discrepancies between height and weight are seen and can help with diagnosis. For example, children who have polyarticular JIA may be of low weight for height, whereas children who have systemic-onset JIA tend to be average in weight for height. The arthritis is most often chronic and symmetrical, and it involves 5 or more joints. Any joint of the body, including the temporomandibular joint and the cervical spine, can be affected. Nearly all children have wrist involvement, and small joint involvement of the hands and feet is common. Finally, these children may develop a chronic uveitis.

#### ***Rheumatoid Factor–Positive Polyarticular Juvenile Idiopathic Arthritis***

Patients who have IgM-RF–positive polyarticular JIA are most often older than 8 to 10 years, are more likely to be girls than boys, and are similar clinically to patients who have adult rheumatoid arthritis. Severe, rapidly progressive, erosive, crippling arthritis; subcutaneous rheumatoid nodules; and rheumatoid vasculitis can develop, just as in adults. Cyclic citrullinated protein (CCP) is a laboratory study that can be used to assess disease severity and potential for joint destruction. An elevated serum level would serve as a reason to institute early and aggressive therapy.

#### ***Rheumatoid Factor–Negative Polyarticular Juvenile Idiopathic Arthritis***

Children who have IgM-RF–negative polyarticular JIA are usually younger. They often have a better prognosis than those who are IgM-RF positive, and typically these children respond better to therapy and have a lower frequency of severe, early, crippling arthritis than do children who have the IgM-RF–positive form. However, they may develop many significant problems. Because IgM-negative polyarticular arthritis starts earlier, it can lead to deformities and problems as a result of the tendency to develop flexion contractures and, if severe, subluxations at the involved joints. Compared with adults, hand involvement affects the interphalangeal joints more often than the metacarpophalangeal joints. Ulnar deviation of the fingers is much less common in children than in adults, whereas flexion contractures, boutonnière (buttonhole) deformities, and radial deviation of the fingers are seen more frequently. Ulnar deviation and subluxation at the wrist may occur. Arthritis of the apophyseal joints of the cervical spine is common and can lead to rapid and significant limitation of extension and rotation. These children are at the highest risk of developing the local and generalized growth problems mentioned previously.

#### ***Oligoarticular Juvenile Idiopathic Arthritis***

Oligoarticular JIA involves 4 or fewer joints, most often the large joints (eg, knee, ankle, elbow), typically in an asymmetric distribution. The pattern and course of

joint involvement are important in distinguishing this form of JIA from the others, as are the number of joints involved. Systemic features are infrequent and, if present, mild. Fifty percent to 60% of all children who have JIA fall in this oligoarticular subgroup, and they have the best overall prognosis. Oligoarticular JIA can be subdivided further into persistent and extended oligoarticular subtypes.

**PERSISTENT OLIGOARTHRITIS.** Persistent oligoarthritis (5%–10% of all patients who have JIA) occurs typically in girls younger than 6 years of age and involves the large joints. These girls are at higher risk of developing chronic uveitis, particularly when positive for ANA. Despite their obvious arthritis, these children generally function well and only rarely complain of significant pain. Little erosive joint damage typically occurs, even though these patients may have ongoing arthritis for many years. Nonetheless, they are at risk for long-term problems, including leg-length discrepancies (a complication of ongoing asymmetric knee joint involvement) and muscle atrophy. The long bone growth plates around the knee with arthritis can become more active because of the inflammatory-associated hyperemia, resulting in increased length of that leg. Similarly, as a result of changes in the child's biomechanics, decreased quadriceps mass on the affected side is frequently found.

Systemic signs and symptoms, except for uveitis, are few. The chronic anterior uveitis is rarely symptomatic until it has progressed to a severe stage, and it may not occur until years after the onset of the arthritis; it may even occur after the arthritis has resolved. Thus, regular ophthalmologic evaluation, including slit-lamp examinations, should be instituted early and continued indefinitely. Because the risk of uveitis decreases with time and varies by JIA subtype and age at diagnosis, the prescribed intervals between examinations range from 3 to 12 months, eventually lengthening after several years if no uveitis is present (Table 324-1).

Except for ANA positivity, few laboratory abnormalities will be found. When positive, the ANA titer is typically low. Although mild increases in white blood cell count and ESR or a low-grade anemia may be observed, results of all of these tests are often normal. HLA-DR5 gene markers appear to confer increased susceptibility for persistent oligoarthritis, whereas HLA-DR1 and -DR4 are underrepresented in this group.

The course of children with persistent oligoarthritis can be extremely variable. Some children have a single episode; others may have recurrent exacerbations and remissions. Regardless of their individual style, this group has the fewest musculoskeletal complications and more long-term remissions compared with the other JIA subtypes.

**EXTENDED OLIGOARTHRITIS.** Children with the extended oligoarthritis subtype of JIA initially have 4 or fewer joints involved in the first 6 months of their disease. However, at different times after the initial 6 months, they develop arthritis in more joints. This group comprises approximately 20% to 25% of all children with oligoarthritis. It differs from persistent oligoarthritis in several ways. Children with this condition appear to have a different genetic makeup, with a higher frequency of HLA-DR1 and a higher

**Table 324-1****Frequency of Ophthalmologic Examination in Patients With Juvenile Rheumatoid Arthritis**

TYPE	ANA	AGE AT ONSET (Y)	DURATION OF DISEASE (Y)	RISK CATEGORY	EYE EXAMINATION FREQUENCY (MO)

Recommendations are to continue follow-up through childhood and adolescence.

From Cassidy J, Kivlin J, Lindsley C, et al; American Academy of Pediatrics Section on Rheumatology and Section on Ophthalmology. Ophthalmologic examinations in children with juvenile rheumatoid arthritis. *Pediatrics*. 2006;117:1843–1845.

occurrence of erosive disease. The additionally involved joints are often the wrists, fingers, and other smaller joints. Although chronic uveitis is seen in fewer cases, it still occurs, and these children also need to be monitored closely by ophthalmologists. Although it seems fewer children in this subgroup enter a prolonged remission than do children with persistent oligoarthritis, they also fare better than children with a polyarthritis onset.

### Enthesitis-Related Arthritis

Enthesitis-related arthritis is a newer classification that includes children who previously were classified as late-onset oligoarthritis. This subgroup includes children with arthritis and enthesitis and the presence of at least 2 of the following: sacroiliac joint pain or inflammatory spinal pain (or both); presence of HLA-B27; history of relatives with HLA-B27-associated disease; anterior uveitis usually associated with ocular pain, redness, or photophobia; or onset of arthritis in a boy older than 8 years. Their arthritis is more frequently in the lower extremities, involving the knees and ankles but also occasionally the toes (resulting in so-called *sausage toe*, or dactylitis).

Complaints and findings of enthesitis (ie, inflammation of the attachment of a tendon, ligament, fascia, or capsule to bone) are a hallmark of this group and may predate any joint problems. These children may progress to fulfill the criteria for ankylosing spondylitis, reactive arthritides, or arthritis associated with inflammatory bowel disease. Approximately 10% will develop an acute iritis. In contrast to the chronic uveitis seen in oligoarticular JIA, this is symptomatic, can be treated early, and is usually self-limited. As with oligoarticular JIA, mild to moderate increase in the ESR is common, but infrequently, other laboratory tests are found to be abnormal.

### Psoriatic Arthritis

Psoriatic arthritis is an additional classification subtype of JIA and bears a similarity to enthesitis-related

arthritis in that large joint inflammation, enthesitis, and dactylitis are often found. For this diagnostic label to be used, however, psoriasis must be present in the child or in family members. Thus, a child can have psoriatic arthritis in the absence of skin disease, though a psoriatic rash can appear at some time after the onset of joint disease. A physical finding that can be useful in identifying psoriatic arthritis in the child or adolescent with characteristic musculoskeletal findings, but no skin eruption, is pitting of the fingernails or toenails. Children are placed in the undifferentiated category if they do not meet the criteria for any of the above subtypes or if they meet criteria for more than 1 subtype.

### Differential Diagnosis

Diseases to be considered in the differential diagnosis of JIA are listed in Box 324-1.

The hallmark of JIA is its chronic nature; the best initial strategy is often careful, watchful waiting. Only by meeting the criterion of sustained arthritis (>6 weeks) and excluding other possible diseases can the pediatrician avoid mislabeling other transient entities as JIA. Other conditions that can mimic JIA in its early stages include the various osteochondroses and avascular necrosis syndromes, musculoskeletal trauma, chondromalacia patellae, Osgood-Schlatter disease, slipped femoral capital epiphysis, diskitis, psychogenic arthralgias, and nonspecific musculoskeletal aches and pains. Hemophilia, sickle cell disease, inflammatory bowel disease, collagen disorders (eg, Ehlers-Danlos syndrome, Marfan syndrome), the autoinflammatory diseases (familial Mediterranean fever, TNF- $\alpha$  associated periodic fever syndrome [Tumor necrosis factor receptor-associated periodic syndrome], hyper-IgD syndrome, Muckle-Wells syndrome, neonatal-onset multisystem inflammatory disease [also known as *chronic infantile neurologic, cutaneous, and articular syndrome*], familial cold autoinflammatory syndrome), Wegener granulomatosis, and sarcoidosis may also be associated with arthritis.

**BOX 324-1 Differential Diagnosis of Juvenile Idiopathic Arthritis****RHEUMATIC DISEASE OF CHILDHOOD**

- Autoinflammatory diseases
- Acute rheumatic fever
- Systemic lupus erythematosus
- Juvenile ankylosing spondylitis
- Polymyositis and dermatomyositis
- Vasculitis
- Scleroderma
- Mixed connective-tissue disease/overlap
- Kawasaki disease
- Behçet syndrome
- Wegener granulomatosis
- Postinfectious reactive arthritis
- Reactive arthritis
- Reflex neurovascular dystrophy/reflex sympathetic dystrophy/complex regional pain syndrome type II
- Fibromyalgia syndrome

**INFECTIOUS DISEASES**

- Bacterial arthritis
- Viral or postviral arthritis
- Fungal arthritis
- Osteomyelitis
- Postinfectious reactive arthritis
- Lyme disease

**NEOPLASTIC DISEASES**

- Leukemia
- Lymphoma

- Neuroblastoma
- Primary bone tumors

**NONINFLAMMATORY DISORDERS**

- Trauma
- Avascular necrosis syndromes
- Osteochondroses
- Slipped capital femoral epiphysis
- Diskitis
- Patellofemoral dysfunction (chondromalacia patellae)
- Toxic synovitis of the hip
- Overuse syndromes

**HEMATOLOGIC DISORDERS**

- Sickle cell disease
- Hemophilia

**MISCELLANEOUS**

- Inflammatory bowel disease
- Chronic recurrent multifocal osteomyelitis
- Sarcoidosis
- Collagen (connective tissue) disorders (eg, Ehlers-Danlos syndrome, Marfan syndrome, etc.)
- Growing pains
- Psychogenic arthralgias (conversion reactions)
- Hypermobility syndrome
- Villonodular synovitis
- Foreign-body arthritis

If the child has a single inflamed joint, then bacterial arthritis must be considered. If any question exists as to an intra-articular septic process, then arthrocentesis must be performed to establish the diagnosis. If *Neisseria gonorrhoeae* is the cause of septic arthritis, then the most common time for this is in adolescence, whereas various strains of staphylococci may be found at any age. Emergence of methicillin-resistant *Staphylococcus* has made antibiotic selection in presumed septic arthritis that much more important. Other infectious agents such as fungi, viruses (including parvovirus, rubella, and hepatitis B), and *Mycoplasma* organisms must also be considered as the cause of arthritis. Lyme disease (*Borrelia burgdorferi* infection) is an etiologic consideration for childhood arthritis in a child living in, or who has recently traveled to, an endemic area. Osteomyelitis, involving the bone contiguous to a joint, and reactive arthritis from a gastrointestinal bacterial infection (eg, *Shigella*, *Salmonella*, *Campylobacter*, or *Yersinia* organisms) may also mimic some subgroups of JIA. Neoplasms involving the bone, either primary or metastatic (eg, leukemia, lymphoma, neuroblastoma), can be accompanied by musculoskeletal complaints. Although arthritis is uncommon and usually transient, complaints of pain that are out of proportion to physical findings and

particularly nighttime pain are common and potentially important clues to heed.

Children who have various immunodeficiencies can have arthritis, either related to their primary problem or as a result of infections. Serum sickness and the various vasculitides, including Kawasaki disease (see Chapter 280) and Henoch-Schönlein purpura (see Chapter 264), can produce intermittent arthritis. Finally, several conditions may produce significant arthralgias and myalgias and may mimic an arthropathy. The complaints and disability resulting from hypermobility syndrome and fibromyalgia can be sufficient to make the clinician believe (although incorrectly) that a form of arthritis is present. Reflex sympathetic dystrophy (also known as *complex regional pain syndrome type II*, or grouped with other amplified musculoskeletal pain syndromes) deserves diagnostic consideration in children who have a hot or cold, pale, painful, and exquisitely sensitive (allodynia) extremity that they refuse to move, particularly when a premorbid history of trauma (often minor) is found.

**Management**

Individualizing each child's management in terms of the disease subtype, extent of activity, clinical course

### BOX 324-2 Medications for Juvenile Idiopathic Arthritis

NSAIDs	CORTICOSTEROIDS

<b>DMARDs</b>	
<ul style="list-style-type: none"> <li>• Hydroxychloroquine</li> <li>• Sulfasalazine</li> </ul>	

DMARDs, disease-modifying antirheumatic drugs; FDA, US Food and Drug Administration; NSAIDs, nonsteroidal anti-inflammatory drugs.

to date, and family situation is always necessary. Although most physicians are accustomed to considering pharmacologic therapy of primary importance, it is only 1 aspect of the treatment of children who have JIA. A multidisciplinary team approach is the most effective way to meet the needs of a child who has chronic arthritis and his or her family. The goal of therapy is to achieve the highest possible level of physical and psychological function for the child.

Currently available drug therapy (Box 324-2), although not yet curative, can suppress the inflammatory activity in many children who have JIA. The ultimate goal is to have no detectable inflammation. Five major categories of drug therapy are available: nonsteroidal anti-inflammatory drugs (NSAIDs), disease-modifying antirheumatic drugs (DMARDs), corticosteroids, immunosuppressive drugs, and agents that possess immune- and cytokine-modulating effects (also known as *biologic agents*). Significant advances continue to take place, particularly in the biologic arena.

Although salicylates are historically the classic NSAIDs, they are no longer the initial NSAIDs of choice because of concerns regarding the development of Reye syndrome and their short half life, and because other agents have emerged that work well. Although these drugs are essentially equivalent in efficacy and toxicity, individual responses to all NSAIDs vary widely. If a child does not improve while receiving

an NSAID within 4 to 6 weeks, then trying others is reasonable. Naproxen, ibuprofen, indomethacin, and meloxicam are available as liquid preparations that can be administered more easily to younger children and to children who have trouble swallowing pills.

Cyclooxygenase II (COX-2)-selective inhibitors decrease the prostaglandin production that mediates inflammation, but in a gastroprotective manner, thereby reducing the risk of gastric erosion or ulcer formation, or both. However, as a result of cardiovascular safety questions, many of these preparations have been removed from the market by their manufacturers. Celecoxib remains available in the United States, and is now approved for use in children with JIA. Meloxicam is predominantly COX-2 selective and is available in a pill or liquid preparation, as well as in a generic form, thereby decreasing cost.

If a child does not quickly respond to NSAID therapy alone or is in a high-risk category, more aggressive interventions are clearly necessary because JIA is neither a benign condition nor one that children will typically “outgrow.” Moving quickly to DMARDs and/or biologic agents, as well as administering intra-articular corticosteroid injections, appears to achieve the goal of no inflammation with great effectiveness.

Although sulfasalazine has seen something of a resurgence, it should not be administered to any child who is sensitive to sulfa drugs or salicylates, whose renal or hepatic function is impaired, or who has conditions such as glucose-6-phosphate dehydrogenase deficiency. Adverse effects caused by sulfasalazine include rashes, nausea, vomiting, and dyspepsia; in boys, a reversible decrease in sperm count is an adverse effect. Bone marrow depression rarely occurs.

Methotrexate has essentially replaced the other traditional DMARDs—intramuscular and oral gold, D-penicillamine, and hydroxychloroquine—as the primary second-line agent in the treatment of JIA. As a competitive inhibitor of dihydrofolate reductase, it exerts both an anti-inflammatory and an immunosuppressive effect on the arthritis. Its efficacy and its dose-response characteristic have been well established. Subcutaneous administration results in high and consistent blood levels and may provide control of the arthritis if oral dosing is ineffective. Hepatic, bone marrow, gastrointestinal, pulmonary, and teratogenic adverse effects are possible. Laboratory monitoring is recommended every 4 to 8 weeks to detect any liver or hematopoietic adverse effects. The administration of folic (or folinic) acid may mitigate a number of methotrexate’s adverse effects, such as nausea and oral ulcers.

Leflunomide, an immunosuppressive agent that inhibits pyridine synthesis and suppresses TNF- $\alpha$  induced cellular responses, has been shown to have beneficial effects similar to methotrexate. However, leflunomide, too, has possible teratogenic effects; it requires ongoing monitoring and is not US Food and Drug Administration (FDA)-approved for use in the treatment of JIA. Other immunosuppressive agents, including azathioprine, cyclosporine, chlorambucil, cyclophosphamide, intravenous immune globulin, thalidomide, and lenalidomide are occasionally administered in specific patients, but they are not currently the standard.

The last decade has brought with it great advances in the understanding of the inflammatory causes of JIA. TNF- $\alpha$  is a major proinflammatory cytokine in both children and adults with arthritis, psoriasis, and a number of other chronic inflammatory diseases. Three biologic agents are currently available to block the activity of TNF- $\alpha$ : etanercept, infliximab, and adalimumab. Etanercept and adalimumab are approved for use in children with JIA, and all 3 agents have demonstrated dramatic improvements in the condition of children and adults with arthritis. Because each agent is slightly different, a child who has not responded or has had an adverse response to 1 agent may still respond well to another. It is now considered standard therapy to add a TNF- $\alpha$  blocker to the regimen of any child with JIA who has not previously responded to DMARD therapy, as well as when tapering the dose of corticosteroids is not possible without precipitating a flare of the disease. Purified protein derivative (PPD) testing is performed before starting these agents because reactivation of tuberculosis is a risk in the setting of TNF- $\alpha$  inhibition. Other adverse effects include injection site pain or reactions, an increased risk of infections, and a possible increased risk of other autoimmune conditions. Long-term effects of TNF- $\alpha$  suppression are not yet known, but more recent data have raised concern for an increased incidence of lymphoma in those patients who have received etanercept, infliximab, or adalimumab. Nonetheless, since their introduction, this class of agents has dramatically altered both the courses of these diseases and the lives of children and adults with arthritis.

Interleukins 1 and 6 are 2 other proinflammatory cytokines that play a significant role in the treatment of JIA. Systemic-onset JIA is more of an IL-1- or IL-6- (or both) driven condition and often responds better to blocking these cytokines than TNF- $\alpha$ . Anakinra, an IL-1-receptor antagonist, has been found to be effective in the treatment of JIA in many children who have not responded adequately to the TNF- $\alpha$  inhibitors. Anakinra should not be administered in combination with a TNF- $\alpha$  inhibitor or any other biologic agent. Canakinumab is a monoclonal antibody also directed toward IL-1 and is recently approved for treating systemic-onset JIA. IL-6 blockade with tocilizumab is an addition to the treatment armamentarium as well.

Abatacept, a biologic agent recently approved for the treatment of children with JIA, works through a different mechanism. It selectively modulates the CD80/CD86:CD28 costimulatory signal required for full T-cell activation. It has demonstrated efficacy in both children and adults with arthritis who have not responded adequately to TNF- $\alpha$  inhibitors.

Rituximab is a monoclonal antibody directed against the CD20 marker on B lymphocytes. Currently approved for adults who have not responded to TNF- $\alpha$  blockade, its use in the treatment of children is yet to be determined.

In the era of monoclonal antibodies, systemic corticosteroid use in JIA has become much less necessary. However, corticosteroids remain important and effective medications, the use of which should follow these maxims: (1) they should only be administered when other agents have failed or when the child is seriously

ill or has progressive severe chronic anterior uveitis unresponsive to local or other systemic therapy; (2) as small a dose as possible should be administered; and (3) their use should be tapered and discontinued as soon as possible.

Corticosteroids are effective anti-inflammatory agents but do not alter the course of the disease. They can be extremely difficult to discontinue in children who have JIA, and their long-term use is associated with many serious adverse effects, including immunosuppression, osteoporosis, and growth retardation. Small daily doses of prednisone may be effective in treating pain and stiffness; higher doses may be needed to manage systemic features such as pericarditis. High-dose intravenous pulse methylprednisolone therapy can be useful in dire situations, but it is not very effective when used as chronic therapy.

Intra-articular corticosteroids have come to play a larger role in the management of JIA, especially oligo-articular JIA. They can be effective in controlling acute problems associated with 1 or several active joints, but they are usually used in combination with systemic, ongoing therapy. Children who have a painful or swollen joint frequently respond to arthrocentesis and instillation of a long-acting corticosteroid preparation (eg, triamcinolone hexacetonide). This procedure should not be performed more than 3 or 4 times per year, and the physician should be absolutely certain that concomitant infectious arthritis is not the cause of the acute joint problem. Early use of intra-articular corticosteroids may even have the potential to modify the course of JIA.

Despite this progress in treatments, there are still children whose disease has proven unresponsive to all of these and other interventions. In a select group, the use of autologous stem cell transplantation has at times proven to be extraordinarily helpful. The risks are great, but for those children, the benefits can be as well.

Because children with arthritis can experience both acute and chronic pain at various times regardless of treatment, this is an important area that needs to be considered and/or addressed. Not all pain is related to the inflammatory aspects of the arthritis. Therefore, before intervening, it is important to determine whether the pain is from the joint inflammation, joint damage or other mechanical factors, periarticular structures, or other issues. Similarly, not all pain requires intervention with medications because various physical or other techniques can also be effective.

Pharmacologic therapy is not the only aspect of the treatment required by children who have JIA. Physical therapy and occupational therapy are crucial adjuncts to help the child maintain strength and range of motion, to prevent contractures, and to allow the best possible quality of life. All patients should be given a home program of therapy that is reviewed and updated regularly. Heat therapy, such as taking warm baths or using a sleeping bag at night, often helps minimize morning stiffness. Swimming is an excellent exercise; affected children should be encouraged to swim and to participate in as many other activities as possible. Normal play is also a form of physical therapy and occupational therapy.

The orthopedist's contributions to patients whose disease is more extensive range from the application of splints to operative tendon releases and capsulotomies. Some children may require joint resurfacing or joint replacement surgery. Even though most children will not need orthopedic intervention (particularly during childhood), the orthopedist's perspective is an important part of disease management.

In all its forms, JIA is a chronic illness, and none of the current modes of therapy is curative. Furthermore, JIA is one of the few childhood illnesses in which pain is a primary symptom. Therefore, different expectations and attitudes are needed when caring for the patient and family. In addition to an attentive and understanding pediatrician, a family counselor, social worker, and psychologist or similar mental health professional are of particular value in helping the child and family to cope with and adjust to this chronic illness. Patients, siblings, and parents may experience feelings of denial, guilt, and frustration at the time of the diagnosis and throughout the course of the disease. Siblings frequently find it difficult to cope with the special and extensive treatment the affected child may receive.

Periodic depression and anger are frequent problems, especially in the early stages as the child and family realize that many changes may be necessary in their lifestyle and dreams, and again as the child enters adolescence. Despite the frequent disruptive episodes brought on by the disease, families are often able to adapt to their child's chronic illness adequately. Poor maternal function, maternal depression, and social isolation are risk factors for poor psychosocial outcomes. A sense of control and mastery are important positive factors.

Most children who have JIA can do well in school; thus, all efforts should be made to keep them enrolled. Studies of children's school and family adaptations show that children who have JIA and their families develop different, albeit generally normal, styles for coping with this chronic illness. Some school adjustments may be necessary, such as arranging for different transportation or physical education (or both) and allowing the child extra time between classes. Having 2 sets of books, one for school and one for home, reduces the work of carrying the books to and from school. The pediatrician or pediatric rheumatology team may have to advocate on behalf of these children within the school so that they can receive all the school services they require.

Although concentrating on scholastic issues is important, these children will require preparation for adulthood. Independent living and vocational preparation must begin in childhood to reduce any potential barriers and difficulties. Anticipatory guidance on transitional issues should be provided starting in childhood and early adolescence.

Although children whose disease is severe have several obvious problems, the child who has mild disease and a hidden disability also may have problems coping, adapting, and trying to accomplish the unrealistic goals set by a society that does not recognize the disability. Any chronic illness imposes many additional stresses on the entire family. The direct and indirect

financial costs alone create significant burdens for the family of any child with JIA and for society.

### Course and Prognosis

Juvenile idiopathic arthritis is rarely fatal, and in general the long-term prognosis is good, particularly for the oligoarticular subtype. Approximately 60% to 75% of children will experience remission at some point, and for many children it will be permanent. Most children who have JIA will complete school, be gainfully employed, and raise families, just as their siblings and peers will.

Several patterns of disease activity are recognized: persistent active arthritis and destructive arthropathy; active disease, then remission; polycyclic diseases characterized by acute flares of activity followed by temporary remissions; and low-grade continued disease activity with little if any joint destruction.

Oligoarticular (not the extended-type) JIA has the best prognosis, with 40% to 50% of children undergoing complete remission, compared with only 25% to 30% of children who have systemic-onset and polyarticular JIA. Children who have IgM-RF positivity, systemic-onset, and certain extra-articular manifestations (eg, persistent fevers, thrombocytosis, subcutaneous nodules, vasculitis), as well as younger children, usually have a poorer long-term articular outcome. Younger children who have systemic-onset and polyarticular arthritis have a poorer articular prognosis. Children who have oligoarticular arthritis and no chronic anterior uveitis have the best prognosis.

Children should be referred to an ophthalmologist at the time of diagnosis. Most clinical uveitis develops within 4 to 7 years of the diagnosis, but it can occur at any time. Therefore, ophthalmologic examinations should be performed indefinitely. Table 324-1 outlines the frequency of eye examinations recommended by the American Academy of Pediatrics. If a child develops uveitis then the child should be monitored according to the ophthalmologist's directions; uveitis can become the child's most vexing problem.

In summary, increasing awareness of pediatric rheumatic diseases has resulted in earlier diagnosis and treatment of JIA. The rapid advances in understanding the diseases and their therapies, especially the promising biologic agents, are encouraging signs that the number of children disabled by these illnesses will decrease in the future.

### WHEN TO REFER

- Persistent oligo- or polyarticular joint inflammation.
- Spiking fevers and rash, but no obvious infectious cause is present.
- Persistent joint pain, limp, or asymmetric use of an extremity for which no explanation has been found.

### WHEN TO ADMIT

- Systemic-onset JIA with the development of severe chest pain with shortness of breath (suggesting pericarditis with hemodynamic

compromise) or a change in voice quality and difficulty breathing (suggesting cricoarytenoid arthritis).

- Systemic-onset JIA with the development of fevers, organomegaly, liver and/or renal dysfunction, markedly elevated ferritin, decreases in red blood cells, white blood cells, or platelets and paradoxical drop in ESR (suggesting the development of macrophage activation syndrome).
- Chronic arthritis for which the child is receiving corticosteroid therapy, and develops signs of severe infection.
- Chronic arthritis for which the child is receiving NSAIDs, and exhibits acute anemia and melanic stools.
- Longstanding polyarticular arthritis complicated by multiple joint contractures and weakness requiring a period of inpatient rehabilitation (eg, physical and occupational therapy).

## SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus is a chronic multisystem autoimmune disorder that affects blood vessels and connective tissues. Children with SLE tend to have a more severe disease course than patients with adult-onset disease. Classic pediatric SLE is defined by its diagnosis before age 21 years.

### Epidemiology

Twenty percent of all SLE patients are diagnosed in the pediatric age group. Pediatric SLE has an incidence that varies with ethnicity between 6 and 30 per 100,000 children per year. The incidence of SLE is higher among black, Hispanic, and Asian patients compared with white patients. The median age at the onset of childhood SLE is 12 years, and 80% of the patients are girls.

### Pathophysiology

The disease is believed to have been caused by interaction between hormonal and environmental factors in a genetically predisposed individual. Hormonal influences like estrogen play a role in disease activity as seen in pregnant patients. There is a higher female-to-male ratio (7:1) in patients presenting in the periparturient period. Men with Klinefelter syndrome may have a higher incidence of SLE. Environmental factors like ultraviolet light exposure, medications, and infections also play a role.

Ten percent of patients with SLE have an affected first-degree relative, and they are also more likely to have a family member with an autoimmune disease. There is a 25% concordance between monozygotic twins.

A dysregulated immune system involving both the T and B lymphocytes leads to activation of innate immunity and release of inflammatory cytokines. This subsequently leads to aberrant activation of adaptive immunity and production of autoantibody. Recent evidence has implicated interferon- $\alpha$  in the development of SLE.

### Clinical Manifestations

In view of its multisystem involvement, SLE mimics many different diseases. It is important to recognize

the disease pattern when a patient presents with multiple symptoms and signs. The American College of Rheumatology classification criteria are a useful tool for the diagnosis. The initial criteria as outlined in Table 324-2 were published in 1982, followed by a revision in 1997.

Children may manifest nonspecific symptoms like fevers, generalized aches, fatigue, weight loss, anorexia, alopecia, and arthralgias. SLE can affect any organ system. Table 324-3 illustrates the frequency of organ involvement in SLE. Pediatric SLE leads to greater renal and central nervous system (CNS) involvement than does adult SLE.

### Monocutaneous Manifestations

Children may develop any type of skin manifestation (Box 324-3), presenting a diagnostic challenge to the pediatrician. SLE is frequently characterized by the classic malar rash that may have a butterfly appearance. It develops on the malar prominence and crosses the nasal bridge sparing the nasolabial folds. It may involve the chin and forehead. The rash is usually nonpruritic and may be macular to maculopapular with associated scaling. It is photosensitive in more than a third of children and may be the first sign of a systemic flare.

Oral and nasal septal mucosa may have painless ulcers. The oral ulcer is generally present on the hard palate. A careful oral examination is therefore necessary so that this important clinical manifestation is not overlooked.

Nonscarring hair loss is common and is often noted in the temporal region of the scalp. It may be global and severe enough to require immunosuppressive therapy.

Discoid rash is a rare manifestation of pediatric SLE and may occur in 10% of patients. This scarring rash occurs on the forehead and scalp and may mimic a tinea lesion. When this rash occurs in isolation without any other systemic manifestations, it is referred to as discoid lupus erythematosus (DLE). Up to 25% of patients with DLE may have pre-existing SLE. The rate of progression to systemic SLE is higher in pediatric patients—up to 24% to 26%, compared with 5% to 10% among adults.

### Musculoskeletal Involvement

Arthralgias and arthritis are common in SLE with symmetric nonerosive and nondeforming involvement of large and small joints like the knees, ankles, wrists, and fingers. It is characterized by stiffness more than pain. Myalgia and myositis are less common. Myositis may occur in the overlap syndrome that has features common to SLE and other rheumatic diseases. The other skeletal features of SLE may be secondary to the disease process and may include avascular necrosis and osteoporosis. Children may experience generalized pain secondary to poor sleep, fatigue, and deconditioning of muscles.

### Renal Disease

Renal disease contributes largely to morbidity and mortality in children with SLE. Renal involvement occurs in 50% to 75% of children with SLE, and more

**Table 324-2** Classification Criteria for Systemic Lupus Erythematosus

CRITERION	DEFINITION
1. Malar rash	Flat or raised erythema over the malar eminences, spares the nasolabial folds
2. Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur
3. Photosensitivity	Skin rash following sunlight exposure, by history or physician observation
4. Oral ulcers	Oral or nasopharyngeal ulceration, usually painless
5. Arthritis	Nonerosive arthritis involving 2 or more peripheral joints, characterized by tenderness, swelling, or effusion
6. Serositis	Pleuritis—convincing history of pleuritic pain or rub on auscultation or evidence of pleural effusion or Pericarditis—documented on electrocardiogram, echocardiogram, or rub
7. Renal disorder	Persistent proteinuria greater than 0.5 g/d or Cellular casts—may be red cell, hemoglobin, granular, tubular, or mixed
8. Neurologic disorder	Seizures in the absence of offending drugs or metabolic derangements or Psychosis in the absence of offending drugs or metabolic derangements
9. Hematologic disorder	Hemolytic anemia with reticulocytosis or Leukopenia less than 4,000/ $\mu$ L on 2 or more occasions or Lymphopenia less than 1,500/ $\mu$ L on 2 or more occasions or Thrombocytopenia less than 100,000/ $\mu$ L
10. Immunologic disorder	Antibody to native DNA or Antibody to Sm protein or Antiphospholipid antibodies—anticardiolipin antibodies, presence of the lupus anticoagulant, or false-positive result on serologic testing for syphilis
11. Antinuclear antibody	Presence of antinuclear antibody on immunofluorescence or an equivalent assay

**Table 324-3** Common Clinical Features of Childhood Systemic Lupus Erythematosus

CLINICAL FEATURES	PREVALENCE OF INVOLVEMENT
Fever	37%–100%
Lymphadenopathy	13%–45%
Weight loss	21%–32%
Mucocutaneous	60%–90%
Musculoskeletal	60%–90%
Nephritis	48%–78%
Neuropsychiatric disease (NPSLE)	15%–95%
Gastrointestinal	24%–40%
Hematologic	50%–100%
Cardiovascular	25%–60%
Pulmonary	18%–81%

From Levy DM, Kamphuis S. Systemic lupus erythematosus in children and adolescents. *Pediatr Clin North Am.* 2012;59(2):345–364, with permission from Elsevier.

than 90% will develop it in the first 2 years after diagnosis. The common manifestations like proteinuria, hematuria, casts, hypertension, edema, renal insufficiency, and renal failure occur secondary to glomerular involvement. Nephritis occurs secondary to deposition of immune complexes of DNA and anti-dsDNA in the mesangium and subendothelial space, ensuing activation of complement, and influx of inflammatory cells. Severity of nephritis does not correlate with the clinical presentation and hence there should be a low threshold for performing a renal biopsy with histologic, immunofluorescent, and electron micrographic analysis. The histologic diagnosis follows a standard classification devised by the International Society of Nephrology and the Renal Pathology Society. It classifies the renal involvement from class I to VI, and this helps guide treatment and prognostication.

The use of aggressive treatment has lowered the incidence of end-stage renal disease but still continues to be 10% to 20% 10 years from diagnosis.

### BOX 324-3 Common Dermatologic Manifestations of Systemic Lupus Erythematosus

- Rash
  - Malar ("butterfly") rash
  - Annular erythema
  - Discoid lupus erythematosus
  - Maculopapular and/or linear (nonspecific) rash
  - Bullous lupus (rare)
- Photosensitivity
- Alopecia
- Raynaud phenomenon
- Palmar/plantar/perioral erythema
- Livedo reticularis
- Vasculitis
  - Petechiae
  - Palpable purpura (leukocytoclastic vasculitis)
  - Chilblains/nodules
  - Digital ulcers

From Levy DM, Kamphuis S. Systemic lupus erythematosus in children and adolescents. *Pediatr Clin North Am.* 2012;59(2):345–364, with permission from Elsevier.

### Neuropsychiatric Involvement

Nineteen distinct syndromes have been described by the American College of Rheumatology Committee on Nomenclature of neuropsychiatric SLE syndromes (NPSLE), as outlined in Box 324-4. Up to 65% of patients develop NPSLE during the disease course. It is the second leading cause of morbidity and mortality associated with SLE. Headache is the most common manifestation and may be of variable severity in 50% to 95% of children with SLE. Headaches can be a symptomatic manifestation of active SLE. They also may indicate increased intracranial pressure and sinus venous thrombosis. The occurrence of new severe headache in children with SLE should be evaluated immediately because of the possibility of thromboembolic events, especially in children with antiphospholipid antibodies. Children with SLE may have mood disturbances primarily because of their struggles with a challenging disease. Psychosis in SLE is unique for its preserved insight. It can occur in association with acute confusional state and cognitive dysfunction. Visual and auditory hallucinations are known to occur in children with SLE. Cognitive dysfunction can be diagnosed with traditional neuropsychological testing and has been found in 59% of patients.

Generalized seizures are more common than focal and occur in association with other SLE syndromes. They may occur with CNS infection, with hypertension, and as part of posterior reversible encephalopathy. Peripheral nervous involvement is rare in SLE.

### Hematologic Features

Hematologic features may be seen in up to 86% of patients with SLE. Cytopenias are common and may occur in up to 60% of patients. Leukopenia is usually

caused by lymphopenia, and less frequently by neutropenia. Lymphopenia may be representative of disease activity whereas neutropenia may be a side effect of medications like cyclophosphamide.

Anemia can be caused by antibody-mediated hemolysis or secondary to chronic disease. Hemolytic anemia has been reported in up to 16% of patients, but generally it is mild and rarely requires blood transfusion.

Immune-mediated thrombocytopenia has a wide range of severity in patients with SLE. Up to 50% of patients may have thrombocytopenia at some stage in their disease course, and 30% may have moderate to severe thrombocytopenia. Children and adolescents with idiopathic thrombocytopenic purpura (ITP) should be tested for antinuclear antibodies, and clinicians should be alert to the possibility of subsequent appearance of other clinical features of SLE. Children with ITP who are older than 10 years are more likely to have chronic ITP. Twenty percent to 30% of patients with ITP who are positive for ANA will progress to SLE.

Diffuse lymphadenopathy may be present in up to 20% of patients. Lymph nodes may be enlarged because of inflammatory changes secondary to SLE, macrophage activation syndrome, or infection.

Up to 40% of patients with SLE may have antiphospholipid antibodies like anticardiolipin antibodies and lupus anticoagulant. Lupus anticoagulant confers a high degree of susceptibility to thromboembolic

events. More than half of all patients with a positive anticoagulant response develop thromboembolic events, of which the majority are venous; approximately 10% of patients with SLE will develop a thromboembolic event. The common thromboembolic events are deep venous thrombi, cerebral venous thrombosis, and pulmonary embolus. Arterial thrombi and stroke are rare in children with lupus.

### **Pulmonary Features**

The various pulmonary manifestations of SLE are pleuritis, pleural effusion, pulmonary hemorrhage, pneumonitis, and pulmonary hypertension. Pleuritis is the most common manifestation, with 17% to 30% of patients developing pleuritis and pleural effusion. Pleuritis and effusion may present with sharp pain, especially on inspiration and dyspnea. Dyspnea also may be secondary to restrictive lung disease, and the lung function tests may demonstrate a restricted diffusion capacity. Restrictive lung disease results from the interstitial pneumonitis and interstitial fibrosis caused by long-standing inflammation. Interstitial infiltrates and pleural thickening may be visible on radiographic examination. Subclinical abnormalities detected on lung function studies may not always progress to active clinical lung disease. Pulmonary hemorrhage is a rare manifestation but may be life threatening, and acute dyspnea with falling hemoglobin levels may be the presenting clinical manifestations.

### **Cardiac Features**

Pericarditis, pericardial effusion, myocarditis, bacterial endocarditis, Libman Sacks endocarditis, and premature atherosclerosis are the cardiac manifestations of lupus. Pericarditis with pericardial effusion is the most common cardiac manifestation and is commonly a cause of chest pain in pediatric SLE. An infarct should also be considered in a patient with chest pain, though the risk is low.

Children with SLE are at risk of developing premature atherosclerosis. Factors that contribute to premature atherosclerosis include the inflammatory and immune abnormalities that are intrinsic to SLE, primary dyslipidemias, and the secondary effects of treatments such as corticosteroids.

Valvulitis that is commonly known as *Libman Sacks endocarditis* is a relatively rare manifestation in pediatric SLE. It may predispose to bacterial endocarditis.

Heart blocks are specific to neonatal SLE.

### **Gastrointestinal Features**

Gastrointestinal involvement may occur in 19% of patients, and may present as peritonitis, vasculitis, pancreatitis, and enteritis. Abdominal pain is found to be the most frequent symptom and occurs in 87% of patients with gastrointestinal involvement. It is mainly the result of peritonitis and pancreatitis. Intestinal vasculitis is a rare complication but may lead to intestinal perforation and hence has to be watched for. Abdominal pain may also be related to side effects of corticosteroids and NSAIDs. In the presence of growth failure and abdominal pain, celiac disease should also be considered.

Liver enzymes may be elevated in 25% of patients secondary to medications, active SLE, fatty infiltration, thrombosis, or infection. Testing for autoimmune hepatitis to facilitate treatment should be considered.

### **Vascular Features**

In SLE, any vessel may exhibit active inflammation. Cutaneous, retinal vasculitis, and small-vessel CNS vasculitis are rare. Thrombotic thrombocytopenic purpura is a rare manifestation of SLE and found in 0.8% of patients with SLE. Although Raynaud phenomenon is not caused by a vasculitis and is primarily representative of vasospasm, it occurs in 19% of patients with SLE.

### **Endocrine Features**

Hypothyroidism is very common in SLE. Diabetes mellitus may develop because of obesity and corticosteroid use. Puberty may be delayed in children with SLE.

### **Diagnosis**

Systemic lupus erythematosus is an illness characterized by flares and remissions, and diagnosis may be delayed because of sequential organ involvement and variation in severity. The delay in diagnosis may range from 1 month to 3 years with a median of 4 months. There needs to be a high index of suspicion and recognition of SLE's disease pattern to be able to make a diagnosis. Most children with SLE fulfill 4 or more of the American College of Rheumatology criteria that were developed for use in research studies. Ferraz and colleagues examined the sensitivity and specificity of the criteria in a group of 103 pediatric patients with SLE and 101 pediatric patients with other rheumatic diseases. They found that the most common criteria were positive ANA, arthritis, immunologic disorder, hematologic disorder, malar rash, and photosensitivity. Sensitivity of the criteria was 96% and specificity was 100% in this analysis.

Some children may present solely with renal disease, manifesting as nephrotic syndrome; rarely a child or adolescent may present with renal failure at the onset of disease.

### **Drug-induced Lupus**

The medications most commonly implicated in drug-induced SLE in children include several of the anticonvulsants (eg, phenytoin and carbamazepine), hydralazine, penicillamine, quinidine, isoniazid, and minocycline. Anti-TNF agents like infliximab, etanercept, and adalimumab may also cause drug-induced lupus. The prevalence of drug-induced disease is equal in boys and girls. Chronic use is required for the disease to develop.

Antihistone antibodies are present in 95% of these children, which differentiates drug-induced from classic SLE. Antineutrophil cytoplasmic antibodies may be positive. The treatment involves discontinuing the offending agent. Rarely anti-inflammatories and corticosteroids may be required. The lupus-like disease induced by these medications should resolve within weeks to months after the medication is discontinued. The drug-induced disease can potentially evolve to the classic form of SLE.

**Table 324-4** Differential Diagnosis of Childhood-Onset Systemic Lupus Erythematosus

INFECTION	GENERALIZED (SYSTEMIC SYMPTOMS)
Viral	Cytomegalovirus Epstein-Barr virus Parvovirus B19 Human immunodeficiency virus Human herpesvirus 6
Bacterial	Sepsis ( <i>Streptococcus</i> , <i>Salmonella</i> ) Brucella Leptospira
Other	Q fever ( <i>Coxiella</i> ) Tuberculosis (mycobacterial) Lyme disease (spirochetal) Toxoplasmosis (protozoan)
Malignant	Leukemia Lymphoma Neuroblastoma Langerhans cell histiocytosis
Autoimmune or inflammatory	Antiphospholipid syndrome Juvenile idiopathic arthritis Juvenile dermatomyositis Sjögren syndrome Mixed connective tissue disease Systemic vasculitis Crohn disease Acute rheumatic fever Sarcoidosis Hemolytic uremic syndrome Antiphospholipid syndrome Autoimmune lymphoproliferative syndrome Common variable immunodeficiency Other primary immune deficiencies Hemophagocytic lymphohistiocytosis
Other	Chronic widespread pain syndrome

From Levy DM, Kamphuis S. Systemic lupus erythematosus in children and adolescents. *Pediatr Clin North Am*. 2012;59:345–364, with permission from Elsevier.

### Neonatal Lupus Erythematosus

The common manifestations of neonatal lupus erythematosus are skin rash, cytopenia, and hepatitis. Congenital heart block may be seen in 30% of infants with neonatal lupus erythematosus. All mothers with positive SSA and SSB need close monitoring during pregnancy. Fetal bradycardia may be the first manifestation and can be treated with dexamethasone. The rash is scaly and papular with raised borders in sun-exposed areas. All manifestations resolve in 6 months except for heart block. These neonates are unlikely to develop SLE. About one-third to half of all children with heart block may go on to require a pacemaker within the first 24 months.

### Differential Diagnosis

The other diseases that may share similarities with SLE are represented in Table 324-4. Table 324-5 lists SLE manifestations with isolated organ involvement without generalized features.

**Table 324-5** Isolated or Focal Symptoms That May Indicate an Underlying or Concomitant Diagnosis of Systemic Lupus Erythematosus

ORGAN SYSTEM	CONDITION
Thyroid	Hypothyroidism (Hashimoto)
Gastrointestinal	Autoimmune hepatitis
Cardiovascular	(Autoimmune) chronic pericarditis Noninfective endocarditis
Hematologic	Immune thrombocytopenic purpura (ITP) Autoimmune hemolytic anemia (AIHA) Evans syndrome (ITP plus AIHA)
Neuropsychiatric	Primary psychiatric disorders (eg, major depression, schizophrenia) Primary central nervous system vasculitis
Lymphoid system	Kikuchi-Fujimoto disease

From Levy DM, Kamphuis S. Systemic lupus erythematosus in children and adolescents. *Pediatr Clin North Am*. 2012;59(2):345–364, with permission from Elsevier.

### Laboratory Findings

Laboratory evaluation in the presence of clinical signs and symptoms may aid in confirming the diagnosis of SLE.

A complete blood count needs to be performed to access the hematologic manifestations of SLE. A metabolic panel to evaluate liver and renal function is also necessary. In addition to hepatitis, elevated transaminases may also indicate muscle inflammation. Inflammatory markers like C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) are adjunct tools. ESR is more indicative of disease activity whereas CRP may be normal except in the presence of active infection, macrophage activation syndrome, or serositis.

Urinalysis is also a very cost-effective test to screen for and monitor renal manifestations of SLE.

### Autoantibodies

Antinuclear antibody is the most common autoantibody, and is present in 99% of patients with SLE. ANA has a high sensitivity (>95%) but low specificity (36%). ANA titers are elevated in 10% of healthy children, and may also be elevated in other rheumatic diseases. Titers of more than or equal to 1:1,080 are highly predictive of SLE. Titers of less than or equal to 1:360, particularly in children younger than 13 years, safely exclude SLE.

Antibodies to double-stranded DNA and extractable nuclear antigens are evaluated in children with elevated ANA titers. Anti-dsDNA antibodies have a high specificity for SLE. This antibody is used for diagnosis and monitoring of disease activity.

Anti-Smith antibody and antiribonucleoprotein (RNP) antibody are ordered together as an extractable nuclear antigen panel. They are highly specific for SLE

and are found in 50% of patients. It is not useful for disease activity monitoring because it remains elevated through the course of the disease. The anti-RNP antibody may indicate the presence of a mixed connective tissue disease whereas the anti-Smith antibody is associated with more severe disease and renal disease.

Other antibodies like anti-Ro (anti-SSA) and anti-La (anti-SSB) are also associated with SLE. Neonates born to mothers with these antibodies are at risk for congenital heart block. Other laboratory test results like low complement levels (C3 and C4) support the diagnosis of SLE. Anti-dsDNA antibody titers and complement levels are very helpful as markers of disease activity as well as for monitoring the disease activity.

### Treatment

The care of the child with SLE requires a multidisciplinary approach and involves primary care, pediatric rheumatology and nephrology, adolescent medicine, psychiatry, psychology, nursing, pain team, physical therapy, and occupational therapy. Pharmacologic treatment is tailored to the disease manifestation. Many immunosuppressant medications used to treat SLE are not approved by the FDA for use in children.

### Nonsteroidal Anti-inflammatory Drugs

These are mainly used for symptomatic treatment of joint pains and serositis.

### Antimalarials

Hydroxychloroquine and chloroquine are used for treatment of mild symptoms and are the key maintenance therapy. Although the mechanism of action is unclear, these drugs may have immunosuppressive, anti-inflammatory, and photo-protective effects. The use of antimalarials has shown a 38% reduction in mortality. They have beneficial effects on the lipid profile by reducing triglycerides, low-density lipoproteins, and very-low-density lipoproteins, and increasing high-density lipoproteins. They help lower the severity of renal disease. They are well tolerated, and the dose should not be increased for weight for obese children because they do not get distributed in the adipose tissue. The common side effects are nausea, vomiting, diarrhea, anorexia, and rarely headaches, dizziness, and elevated liver enzymes. It is important to monitor patients every 6 to 12 months for retinopathy, which is an uncommon but important side effect. The risk of retinal changes is rare at doses lower than 6.5 mg/kg. The risks are higher with liver and renal dysfunction, high cumulative doses, and long duration of therapy. The changes start in the paracentral region of the retina and cause central visual field loss. The other rare side effects are neuromyopathy and cardiotoxicity.

### Corticosteroids

These form the mainstay of therapy when rapid control is required. More than 95% of children require corticosteroids at some stage in their disease. The use of oral versus intravenous corticosteroids differs significantly among different pediatric rheumatology centers. The

dose and duration depend on the organ and disease being treated. Oral corticosteroids are the drugs of choice for SLE-associated skin, serosal, pulmonary, hematologic, renal, and cerebrovascular disease. Corticosteroids are used in combination with immunosuppressive drugs for severe organ involvement. Since the 1970s, the so-called *pulse corticosteroids*, or intravenously administered methylprednisolone at a dose of 10 to 30 mg/kg (max, 1 g), have been used mainly for severe disease exacerbation. Corticosteroids do improve the clinical manifestations of SLE, but the long-term and short-term side effects affect the child's well-being. The long-term use of corticosteroids is associated with fractures related to osteoporosis, avascular necrosis of joints, cataracts, glaucoma, and coronary artery disease.

### Immunosuppressive Agents

Immunosuppressive agents are given to improve outcomes of renal disease and neuropsychiatric SLE. They also act to lower the total cumulative doses of corticosteroids in disease manifestations that flare up with corticosteroid tapering.

- Methotrexate is used for persistent arthritis.
- Azathioprine is used for arthritis, cytopenia, vasculitic rash, and serositis.
- Mycophenolate mofetil (MMF) is used for induction of remission in lupus nephritis, and for maintenance therapy of other organ disease. Hispanic and black children may respond better than white children to MMF.
- Cyclophosphamide, an alkylating chemotherapeutic agent, is used for severe life-threatening involvement like neuropsychiatric manifestations of psychosis and acute confusion. It may be used for lupus nephritis that has responded poorly to MMF.

B cells play a role in generation of autoantibodies in SLE, therefore, anti-B-cell antibody rituximab has also been used for disease with multiorgan involvement that is refractory to corticosteroids and other immunosuppressive therapy. Cyclophosphamide had been used in the past in more than half the patients. Belimumab and anti-B lymphocyte stimulator antibody has been shown to be effective in SLE with mild to moderate symptoms. They have not been studied in children.

### Adjunctive Therapy

For children with nephritis, antihypertensive agents and a low-salt diet may be required. Angiotensin-converting enzyme inhibitors are effective in reducing proteinuria. Lipid-lowering agents are not uniformly prescribed.

For children with neuropsychiatric SLE, psychotropic drugs may be needed, along with anticonvulsants for seizures.

Children with antiphospholipid antibodies or history of thrombi will need anticoagulation with close monitoring.

Patient should consider using contraception based on their individual situation when teratogenic agents are being used. Estrogen-containing agents are acceptable for patients who do not have antiphospholipid antibodies. When there is a risk for thrombosis, progesterone-only alternatives need to be considered.

### Course and Prognosis

Children with SLE have a more severe disease course than adult-onset SLE. Nonwhite race is associated with a worse outcome, but socioeconomic status may be a confounder. Mortality rates have decreased over time, and the current 15-year survival rate is 85%. Mortality in the early years after diagnosis is related to infections, severe lupus exacerbation, and end-stage renal disease. Late mortality is caused by cardiovascular disease. Premature atherosclerosis plays a large role in the increased risk of myocardial infarction in women in their 30s and 40s.

Long-term complications include end-stage renal disease needing dialysis and transplantation. The morbidity in patients with lupus results from a combination of the disease itself and adverse effects of its treatment like osteoporotic fractures, avascular necrosis, and infections. There is an increased risk of malignancy, particularly lymphoma, in these patients.

These children have poor mental and physical functioning. Education is negatively affected, and they eventually require disability support. Health-related quality of life scores are low in these patients.

### Role of the Pediatrician

The pediatrician, along with rheumatologists, plays a key role in the management of children with SLE. The office visit should be used to screen for common complications of the disease and side effects of treatment. Immunizations need to be up to date. Live virus vaccines are contraindicated for patients taking immunosuppressive medications. Children with fever need a careful evaluation for overwhelming sepsis and judicious use of antibiotics.

Families also need help navigating the educational system to establish an Individualized Education Program if the child is adversely affected by the chronic disease. Children's emotional state should be monitored in case psychological help is needed with coping skills.

### Summary

Systemic lupus erythematosus is a lifelong chronic autoimmune disease with unpredictable episodes of flare-ups and remissions. It is more aggressive in children. In view of the unique needs of adolescents, it needs to be managed carefully. Long-term outcome data are being sought, which will help better care for these patients.

#### WHEN TO REFER

- A child with persistent unexplained hemolytic anemia, thrombocytopenia, or neutropenia
- A child with persistent joint pain and other symptoms referred to multiple systems
- A child with malar skin rash
- Any constellation of signs and symptoms where lupus may be suspected

#### WHEN TO ADMIT

- Workup of a child at presentation when the diagnosis is uncertain and the child is sick

- Fever in a child with a diagnosis of SLE on immunosuppressant
- Active disease with poor control of symptoms and failure of outpatient management
- Treatment of an acute disease exacerbation where parenteral medications may be necessary
- Treatment of acute organ involvement leading to renal failure, pulmonary hemorrhage, or cerebrovascular stroke

### TOOLS FOR PRACTICE

#### Engaging Patient and Family

## Chapter 325

# ROCKY MOUNTAIN SPOTTED FEVER

Robert T. Seese, MD; Lara Danziger-Isakov, MD, MPH

### INTRODUCTION

Rocky Mountain spotted fever (RMSF), an acute infectious disease caused by *Rickettsia*, is characterized by fever, headache, myalgia, and a distinctive exanthem. The major pathologic lesion, vasculitis, makes RMSF a multisystem disease. Most important, RMSF requires clinical diagnosis and treatment before laboratory confirmation.

RMSF is an infectious disease that produces a vasculitis, giving rise to symptoms in multiple organ systems, including skeletal muscle, brain, lungs, kidneys, adrenal glands, liver, and heart. *Rickettsiae* multiply in endothelial cells and may produce cellular injury by various mechanisms. These mechanisms include cell

wall penetration, disturbance of intracellular metabolism, production of toxic metabolites, and use of metabolites required by the host cell. Necrosis of endothelial cell walls, an increase in vascular permeability, fibrin extravasation, and thrombosis of small blood vessels ensues because of perivascular mononuclear cell infiltration caused by the reproducing organism. Resulting cell damage in multiple locations is responsible for the clinical picture.

## INCIDENCE

The disease was first reported in patients from the Rocky Mountain region. Today, however, the incidence of the disease is greatest east of the Mississippi River, with most cases being reported from the southeastern and south central United States. The reported frequency of the disease in the United States has increased slightly during the last several years from more than 500 cases per year in the 1990s to more than 1,000 cases per year since 2000. This translates to an increase from less than 2 cases per 1 million persons in 2000 to more than 6 cases per 1 million persons in 2010. From 1994 to 2003, 54% of the cases of RMSF reported in the United States were in North Carolina, Tennessee, Oklahoma, South Carolina, and Arkansas. Although the disease occurs predominantly in the United States, it has been reported in other areas in the Western Hemisphere, specifically Canada, Central America, and South America.

## EPIDEMIOLOGIC FEATURES

Ticks serve as a vector for the infectious agent *Rickettsia rickettsii*. Transmission to humans occurs when the tick takes a blood meal or when the abraded skin is contaminated by tick feces or a crushed tick, which may occur when ticks are removed. Usually, tick attachment lasting 12 to 24 hours is needed to transfer the disease to a human host. Two specific ticks serve as major carriers: the wood tick, *Dermacentor andersoni*, is the more important vector in the western United States; the dog tick, *Dermacentor variabilis*, is the usual vector in the eastern United States. Ticks, in turn, acquire the rickettsiae by feeding on infected wild mammals, such as squirrels, opossums, rabbits, dogs, and mice. Infection of laboratory workers has been reported independently of exposure to ticks. The seasonal incidence of RMSF, which occurs primarily in spring, summer, and fall, is in accordance with the activity of ticks. Dog ticks infected with *R. rickettsii* have been found in urban areas, which suggests this tick's ubiquitous nature and places individuals at risk without travel to endemic areas. Additional work has also implicated the brown dog tick, *Rhipicephalus sanguineus*, in causing an outbreak of *R. rickettsii* infection in Arizona in 2002 through 2004.

In adults, occupational or recreational exposure to ticks increases the risk for infection; however, children are the most frequently affected, with two-thirds of cases occurring in children younger than 15 years, and peak ages of infection of 5 to 9 years. Fifteen percent of deaths from RMSF occur in children younger than 10 years. The illness occurs more frequently in boys than girls and more in white people

than people of other races. RMSF can occur at any time of the year, but 90% of cases occur from April to September.

A study by Marshall and colleagues described positive serologic tests for RMSF in 12% of healthy children living in the southeast United States. This finding seems to indicate that many infections may be subclinical.

Exposure to a tick is not elicited in every case. Only 60% of patients with RMSF can recall a specific tick exposure or encounter. The tick bite is painless and leaves no local lesion or regional lymphadenopathy; the clinician should therefore question the patient specifically about prior activities that increase the risk for exposure (eg, removal of a tick from a pet dog, camping or picnicking in a high-risk area). The overall risk to patients, even when in high-risk areas, is low, given that only approximately 1% to 3% of the tick population carries *R. rickettsii* at any given time.

## DIFFERENTIAL DIAGNOSIS

Illnesses to be considered and differentiated from RMSF, especially after the rash appears, include rubeola (measles), meningococcemia, Kawasaki disease, leukemia, typhus, ehrlichiosis, and infectious mononucleosis.

### Meningococcemia

The petechial rash of meningococcemia differs from that of RMSF in its distribution, rapid extension, and coalescence of lesions into larger hemorrhagic, purpuric areas. Prostration develops rapidly if the patient remains untreated and is often apparent on admission to the hospital. Absence of myalgia and an extremely abrupt onset are helpful points in differentiating meningococcemia from RMSF. Although the white blood cell count may be elevated in meningococcemia, the sickest patients are frequently leukopenic. Meningitis with pleocytosis, low glucose levels, and organisms in the cerebrospinal fluid (CSF) also may be present. However, distinguishing between these entities clinically is not often possible; therefore treatment of both diseases in an ill patient is warranted.

### Ehrlichiosis

Ehrlichiosis is a rickettsial disease with clinical similarity to RMSF. Although a rash occurs with less frequency, more than 60% of children with ehrlichiosis have been noted to have rash. The rash, although variable in location and appearance, may be petechial and can be confused with rickettsial exanthems. Early diagnosis and treatment of patients with ehrlichiosis with doxycycline (also the drug of choice for RMSF) reduces morbidity.

### Rubeola

Rubeola (measles) is characterized by a macular rash (infrequently becoming hemorrhagic), which begins on the face and neck and is preceded by an enanthem, and Koplik spots on the buccal mucosa. The coryza and cough in the prodromal stage of illness are not consistent with RMSF. A history of adequate

immunization with rubeola vaccine greatly diminishes this possibility.

### Kawasaki Disease

Kawasaki disease shares many of the features of RMSF: fever, puffy hands and feet, rash, and conjunctival infection. Usually, Kawasaki disease is not considered seriously until after 5 days of fever, and an enlarged cervical node, pharyngeal hyperemia, dry cracked lips, strawberry tongue, and marked irritability tend to suggest the diagnosis. Although patients with Kawasaki disease also have a rash, it typically does not begin peripherally and spread centrally or become petechial in 1 to 2 days. Leukocyte and erythrocyte sedimentation rates are usually elevated significantly. In addition, Kawasaki syndrome usually occurs in the winter and spring months, in contrast to RMSF, which peaks during the summer. Typically, children with Kawasaki disease do not give a history of tick exposures. An elevated platelet count begins during the second week of illness. (See Chapter 280 for a more detailed discussion of Kawasaki disease.)

### Other Illnesses

Other illnesses that produce petechiae must also be mentioned, even though they lack the distinctive distribution of the rash. Patients with leukemia who initially have fever and petechiae would be expected to be anemic and have lymphadenopathy or hepatosplenomegaly. Patients who have infectious mononucleosis, if they have a petechial eruption, usually have lymphadenopathy, hepatosplenomegaly, and a gradual onset. Typhus is a rickettsial infection to be excluded. Murine typhus produces a milder disease, with a rash that is macular and not petechial. Epidemic typhus may produce a petechial rash that typically begins proximally and extends peripherally but does not usually involve the palms or soles; a history of a tick bite is also absent.

## CLINICAL FEATURES

After inoculation with the rickettsiae, the incubation period ranges from 2 to 12 days; the usual period is 5 to 7 days. In general, shorter incubation periods are associated with more serious disease.

In the typical case, the prodromal period lasts 2 to 3 days, with low-grade fever, chills, and muscle aches predominating. Muscle pain is most commonly in the calf region in younger patients. Headache is also an early symptom, and infants and toddlers may express pain from this or myalgias as crying or fussiness. Malaise, anorexia, vomiting, and photophobia also frequently occur. The prodrome is followed by accentuation of symptoms, especially fever, with temperatures often as high as 40°C (104°F) or more. The lowest temperatures, although still elevated, are recorded in the mornings. Lethargy and mental obtundation become prominent. Although the symptoms seen at this stage are not diagnostic, the triad of fever, headache, and myalgia, combined with a history of tick bite or removal within the previous 2 weeks, mandates treatment for RMSF until the diagnosis can be excluded.

Of RMSF symptoms and signs, rash is most distinctive. It usually appears 3 to 5 days after the onset of fever and begins peripherally on the wrists, ankles, hands, and feet. Initially, the lesions are macular, discrete, and erythematous and blanch on pressure. The rash rapidly spreads centrally, involving the arms, legs, axillae, buttocks, trunk, neck, and face. The lesions deepen in color, becoming dusky red, maculopapular, and petechial, but true petechiae may not form until day 6 of illness, and 35% to 60% of patients never develop petechiae. When present, petechial lesions may coalesce and form large ecchymotic areas. In severe cases and when treatment is delayed, these ecchymotic areas may ulcerate, and distal regions (eg, fingers and toes) may become gangrenous in as many as 4% of cases. Furthermore, as many as 15% of patients do not develop rash, or they develop a fine rash that may be difficult to appreciate in patients with darker skin tones. Because the rash does not typically occur until day 4 of the illness (and petechiae may be a much later finding) and some patients never develop a discernible exanthem, the pediatrician must not withhold treatment of a suspected case of RMSF until the rash appears. Tachycardia and an elevated pulse rate are noted early and are proportional to the degree of hyperpyrexia. A sudden increase in pulse rate or a decrease in blood pressure may indicate peripheral circulatory collapse, severe bleeding, or myocardial failure. Photophobia is associated with conjunctival ecchymosis involving both bulbar and palpebral conjunctivae. Retinal hemorrhages also may be seen.

Abdominal pain, vomiting, hepatomegaly, and splenomegaly with generalized abdominal tenderness may occur. Jaundice is not usually seen except in the most critically ill patients, such as those with disseminated intravascular coagulation (DIC). Fever, poor fluid intake from nausea, and vomiting all contribute to a diminished urinary output. Mild azotemia caused by these fluid losses should respond to rehydration.

In addition to the lethargy and obtunded state of consciousness, the patient may exhibit nuchal rigidity as a result of a vasculitic reaction in the meninges. Disorientation and confusion, as well as seizures, may occur. Coma, central deafness, cortical blindness, and sixth nerve palsies are other neurovascular complications that have been reported with RMSF. Vasculitis, hemorrhage from coagulopathy, or secondary metabolic changes caused by circulatory collapse are responsible for these neurologic manifestations. When these symptoms occur early in RMSF, they may mask its diagnosis.

## LABORATORY EVALUATION

The diagnosis of RMSF is made clinically. Treatment should be started before laboratory diagnosis is confirmed because there is significant morbidity and mortality and a confirmed diagnosis is usually only made on the basis of a rise in antibody titer. Available laboratory tests to confirm the presence of *Rickettsia* include a rise in antibody titer detected by immunofluorescence or latex agglutination, polymerase chain reaction testing, immunofluorescence of a skin biopsy,

or isolation of the organism from a clinical specimen. Immunofluorescent staining or polymerase chain reaction testing of the skin biopsy specimen may identify *R. rickettsii* and may provide early proof of RMSF, but these studies are not readily available to most physicians. Appropriate antibiotic therapy started 3 days before biopsy has resulted in negative immunofluorescence. Therefore when appropriate treatment has been initiated before biopsy, clinical criteria justify a full course of antibiotic therapy.

Complement fixation and immunofluorescent antibody studies in serum will identify patients who have RMSF, but results of these tests do not become positive until 7 to 10 days after the onset of illness, or later if antibiotic therapy has begun early. Thus titers should be performed during the acute illness and repeated 3 weeks later. A 4-fold increase in titer in the convalescent sera is diagnostic for infection.

The Weil-Felix reaction, agglutination of *Proteus vulgaris* by the patient's serum, is at best a nonspecific test for RMSF. Again, acute and convalescent serums must be compared, although *Proteus agglutinins* may appear by the end of the first week of illness. Availability of the more specific and sensitive tests makes this test obsolete.

*Rickettsiae* can be isolated from body fluid or tissue specimens when grown in laboratory animals or chick embryos. However, the high rate of disease transmission to laboratory technicians makes such techniques feasible only in laboratories engaged in *Rickettsia*-related research in which all workers are immunized; thus culture identification of *rickettsiae* is not available in most clinical settings.

Blood leukocyte counts and differential counts are usually within normal limits, but neutrophils often predominate. This predominance may help distinguish RMSF from ehrlichiosis, given that most patients with ehrlichiosis have lymphopenic leukopenia. Thrombocytopenia is a complication seen in the later stages of the disease and may be the result of platelet adherence to damaged endothelium.

Up to 20% of patients may have hyponatremia, possibly caused by increased vascular permeability of the kidney to sodium. However, this finding is nonspecific and does not exclude other diagnoses, such as ehrlichiosis. The remainder of the electrolyte profile is usually normal, but hypochloremia is also seen in some patients. Up to 25% of patients will also display increased blood urea nitrogen levels and increased liver enzymes. Abnormalities of prothrombin time, partial thromboplastin time, fibrinogen, and fibrin split products can occur with the development of DIC.

Patients with neurologic manifestations may have normal CSF cell counts, and most have normal CSF glucose and protein levels. However, CSF analysis may reveal neutrophilic or lymphocytic pleocytosis and elevated protein. As with many of the laboratory findings, these are nonspecific and may not help distinguish RMSF from meningococcal disease or ehrlichiosis.

Hematuria and anemia also may occur, but transfusion or renal dialysis is rarely required.

## MANAGEMENT

### Treatment

Treatment should never be withheld or delayed because of absence of rash, lack of exposure to ticks, or the desire to await confirmatory laboratory study results. Furthermore, delaying treatment is not acceptable because the patient is not from an area where RMSF is common or because the pediatrician is uncomfortable using doxycycline in a child younger than 8 years. If a pediatrician strongly suspects RMSF because of the patient's clinical history and physical findings, then therapy should be initiated immediately and can be given concurrently with treatment for meningococemia.

### Pharmacotherapy

#### Doxycycline

The drug of choice for all ages is doxycycline, an antibiotic in the tetracycline class of antibiotics that is given and continued for at least 3 days after clinical improvement and defervescence. The usual length of therapy is 7 to 10 days. Intravenous therapy should be given to all ill patients, who should then be transitioned to oral therapy when their condition has improved. Doxycycline is also effective against ehrlichiosis, which may mimic RMSF. Because doxycycline has a broad therapeutic index, levels do not need to be monitored as required with other RMSF medications, such as chloramphenicol.

#### Tetracycline

Tetracycline has been shown to be effective against RMSF but can lead to increased dental staining compared with doxycycline in children younger than 9 years. For this reason, and because tetracycline is no more effective than doxycycline, tetracycline is less commonly used in children.

#### Chloramphenicol

Chloramphenicol is no longer the drug of choice for RMSF. Data have shown doxycycline may be more effective than chloramphenicol. In addition, the toxic effects of this drug (aplastic anemia) make it an undesirable treatment option. However, chloramphenicol may be given to patients who cannot tolerate doxycycline or tetracycline.

#### Combination Therapy

Initiating treatment for meningococcal disease, as well as RMSF and ehrlichiosis, in an ill patient may be necessary. When this situation arises, doxycycline will provide treatment for both ehrlichiosis and RMSF and can be used in conjunction with an extended-spectrum cephalosporin to treat meningococcal infection.

### Hospitalization

Hospitalization is desirable initially for most patients, both to confirm the diagnosis and to observe the effect of therapy. Therapy should be continued until the patient has improved and has been afebrile for 72 hours, which generally corresponds to a total of 7 to 10 days of therapy.

### Supportive Therapy

Supportive therapy includes maintenance of hydration and nutrition with appropriate intravenous fluids and oral feedings (if tolerated). Management of DIC may include therapeutic maneuvers such as administering fresh-frozen plasma, fresh platelets and packed red blood cells, and vitamin K. Seizures may require the use of anticonvulsant medications.

### PROGNOSIS

Rocky Mountain spotted fever now has a mortality rate of approximately 0.5% to 4% in recognized cases, but patients with RMSF who escaped clinical detection have been identified by serologic evidence, suggesting that the disease may occur in a mild or subclinical form. The importance of abdominal pain mimicking an acute abdominal condition and dominating as an early symptom before the development of a rash must be emphasized. Rocky Mountain spotless fever has also been described. Of great concern is a report suggesting that patients who have *spotless* or *almost spotless* fever have a significantly higher mortality as a result of delayed diagnosis and treatment.

RMSF is a potentially lethal illness, even though younger patients are likely to be less severely affected than older patients. Early diagnosis and prompt therapy lessen disease severity. Under such circumstances, death would be extremely unusual; in most patients, early clinical diagnosis and adequate therapy shorten the duration of illness appreciably. Normal temperatures within the first 3 to 4 days may be expected, and patients recover rapidly from other signs of illness (eg, headache, myalgia, lethargy). Extension of the rash ceases. Recovery from the illness is accompanied by immunity to *R. rickettsii*.

### COMPLICATIONS

Vascular necrosis and thrombosis may result in local gangrene and loss of tissue. Although uncommon, DIC may develop. Patients with this complication have the greatest risk for dying. Myocardial failure may result from myocarditis and arrhythmias. Edema may be generalized as a result of an increase in capillary permeability caused by the vasculitis, of heart failure, of iatrogenic fluid overload, or any combination.

Neurologic complications in addition to the lethargy have already been discussed, but long-term morbidity from these complications, although rare, is still significant. Hematuria and anemia also may occur, but transfusions or renal dialysis are rarely required.

### PREVENTION

N-N-diethyl-M-toluamide (DEET) skin repellents in conjunction with permethrin-containing repellents used on clothes has been shown to be effective against ticks. Systemic reactions to DEET are possible when the repellents contain a high concentration of the chemical. The best preventive measure is avoidance of tick exposure, but when exposure is likely, daily searches for ticks should be performed. For tick-infested areas, twice-daily searches are

advised. Careful inspection at bath time is an excellent way to discover the presence of ticks. They may be removed by gentle traction with forceps or tweezers, but care must be taken not to crush them. The skin should be disinfected both before and after tick exposure to clear it of tick feces that may carry *R. rickettsii*. The tick should never be covered in petroleum jelly, nail polish remover, or alcohol, and no one should attempt to burn the tick to coax it to detach itself. These attempts may lead the tick to defecate or aerosolize infected body fluids. Antimicrobial prophylaxis is not indicated after a tick bite. The chances of a tick carrying the disease, even in an endemic area, are low, and no demonstrable benefit of prophylaxis has been found.

#### WHEN TO REFER

- Uncertain of diagnosis
- Clinical suspicion of disease

#### WHEN TO ADMIT

Most patients need to be hospitalized until they show clinical improvement. Other indications for hospitalization include:

- Hemodynamic instability
- Dehydration
- Need for intensive monitoring
- RMSF with its complications

## Chapter 326

## SEBORRHEIC DERMATITIS

Elizabeth Alvarez Connelly, MD; Lawrence A. Schachner, MD

Seborrheic dermatitis (SD) is a common, usually asymptomatic dermatosis of unknown cause that is seen primarily in infants but also in adolescents and adults. The incidence in the general population is 2% to 5%. In 50% of affected infants, symptoms begin before 5 weeks of age. Although SD is occasionally seen in infants who are infected with human immunodeficiency virus (HIV), a true increased incidence has not been documented. No evidence suggests a genetic predisposition. Infants with SD may be at an increased risk for developing atopic dermatitis and, less often, psoriasis.

## EVALUATION

Most commonly, SD is characterized as a greasy, scaly dermatitis, less often as psoriasiform SD and rarely as erythrodermic SD. Seborrheic dermatitis in infancy, known as cradle cap, is characterized by diffuse, red, crusted, and yellow scaling plaques on the vertex of the scalp (Figure 326-1). Similar lesions also may be found in the retroauricular creases, the eyebrows, and the nasolabial folds (Figure 326-2). In the axillary and inguinal folds, the neck, and the diaper area, lesions appear as shiny red patches with foul-smelling scales. Posterior lymphadenopathy has been shown to be significantly associated with SD in children with a negative fungal culture. The lesions are usually asymptomatic and distributed symmetrically. The presentation is similar in adolescents. A greasy, scaling, pruritic eruption may be noted on the scalp. Except for lack of inguinal area involvement, the distribution of the lesions is the same as that for infants. Human immunodeficiency virus (HIV)-positive children aged 2 to 5 years may exhibit SD with lesions similar to those seen in adolescents and adults. This circumstance is distinctly unusual in

immunocompetent children and seems to be a manifestation of HIV infection.

Psoriasiform SD, also known as *sebopsoriasis* or *seborrhiasis*, produces features of both SD and psoriasis and may represent a bridge between the 2 conditions. Psoriasiform plaques—annular, red-brown plaques with a silvery scale—may be present among the classic greasy, yellow, scaling lesions of SD. Children may or may not have *pitted* nails, which are seen with classic psoriasis. Erythrodermic SD is rare and causes widespread exfoliative erythroderma. Diffuse desquamation usually begins in the flexures and then spreads.

The child may exhibit signs and symptoms of systemic involvement: fever, chills, lymphadenopathy, peripheral edema, and dehydration. This involvement may also be the presentation of Leiner disease (see Differential Diagnosis).

## ETIOLOGY

The cause of SD remains unknown. In recent years, different pathogenic mechanisms have been proposed. Despite early evidence that *Pityrosporum ovale* may play a role in the evolution of SD, recent data support a causal link between *Malassezia* yeast and SD. Many studies have demonstrated clinical improvement of SD when interventions reduce *Malassezia* counts on the body. Separate research has shown that the use of antifungal agents effectively treats SD. However, no difference has been found in the *Malassezia* carriage rates in children with and without SD. Thus, authorities have proposed that the immunomodulatory factors of the host may influence the manifestation of SD rather than the actual colonization counts. *Malassezia* may serve as the primary trigger in an inflammatory reaction that ultimately results in SD. Studies have revealed an increase in both lymphocyte transformation response and leukocyte migration inhibition. This differing immunogenic host theory may explain the increased prevalence of SD in patients with acquired immunodeficiency syndrome. Other research postulates that SD lesions are induced by the toxin production or lipase activity of *Malassezia*. Seborrheic dermatitis lesions tend to be located on

**Figure 326-1** Cradle cap.

**Figure 326-2** Seborrheic dermatitis in the retroauricular creases, eyebrows, and nasolabial folds.

the scalp, face, eyebrows, and nasolabial, axillary, and inguinal folds. These locations are also areas of highest sebaceous gland concentration. Experts have proposed that an abnormality in the sebaceous gland or an increased sensitivity to circulating maternal or endogenous hormones may result in SD. However, children with SD have normal sebaceous secretion and hormonal levels.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis of SD includes atopic dermatitis, psoriasis, dermatophyte infection, diaper dermatitis, and Langerhans cell histiocytosis. Atopic dermatitis is usually distinguished by the presence of extreme pruritus, extensoral distribution in infancy, and flexural distribution in older children (tending to spare the scalp and involve the hands and feet), as well as a family history in 70% of persons affected. Seborrheic dermatitis may also occur concomitantly with atopic dermatitis (see Chapter 219, Atopic Dermatitis). Psoriasis is a common inherited papulosquamous skin disorder characterized by well-demarcated, annular, thick, red-brown, scaling plaques usually present on the trunk, the extensor areas on the arms, knees, elbows, diaper area, and scalp, as well as by nail pitting. Psoriasis usually lacks the specific distribution and greasy component of SD. However, some cases of SD may overlap with psoriasis. Extensive cases of SD become persistent; when the family history of psoriasis is positive, children should be referred to a dermatologist for biopsy and, potentially, long-term follow-up care. Symptoms of dermatophyte infection of the scalp (tinea capitis) may include scaling, pruritus, and redness and usually results in alopecia. In addition, performing a fungal culture by swabbing the affected area vigorously will yield a positive result. Tinea corporis appears as annular, red, scaly plaques with central clearing. Cultures from the skin may be obtained in a similar fashion to the scalp. Potassium hydroxide preparation of scales from body lesions will demonstrate septate hyphae.

Diaper dermatitis, or irritant diaper rash, is characterized by involvement primarily of the convex surfaces by red, scaling plaques; the inguinal folds are spared (Figure 326-3). In candidal diaper dermatitis, similar red, scaling plaques involve the skin folds, but satellite pustules in areas not covered by the diaper may also be found (Figure 326-4). Seborrheic dermatitis in the diaper area involves the skin folds; however, no satellite lesions are found. Langerhans cell histiocytosis refers to Letterer-Siwe disease (diffuse disseminated histiocytosis), Hand-Schüller-Christian disease, and eosinophilic granuloma (chronic multifocal or focal histiocytosis). Letterer-Siwe disease may be confused with SD because its pattern of distribution is similar. However, Letterer-Siwe disease is also characterized by axillary, inguinal, and oral mucosal erosions, purpura and petechiae, and hepatosplenomegaly. A skin biopsy specimen will distinguish the 2 disorders easily and is recommended in cases of SD that are unresponsive to treatment. Erythrodermic SD is an inherited immunologic disorder characterized by generalized SD, persistent diarrhea, failure to thrive, and recurrent

**Figure 326-3** Irritant diaper dermatitis.

**Figure 326-4** Candidal diaper dermatitis.

gram-negative infections. The diagnosis is made by demonstrating deficient yeast opsonic activity in the child's serum. In addition, other immunodeficiencies and metabolic disorders may occur in an erythrodermic SD pattern.

## TREATMENT

Effective treatment for SD may involve a wide range of keratolytic agents, low-potency corticosteroids, and antifungal therapies. Medication choice is tailored to fit the age of the child. A more conservative approach is suggested when treating infantile SD (cradle cap). Applying mineral oil or white petrolatum to the scalp followed by a nonmedicated shampoo is an initial therapy. If the SD is unresponsive to this therapy, then second-line agents include a 1% to 2% salicylic acid in liquid or petrolatum form, followed by a keratolytic shampoo and a topical low-potency corticosteroid (1%–2.5% hydrocortisone or fluocinolone acetonide). Topical antifungals, specifically the azoles, are effective as well. More recently, the use of topical macro-lactam immunomodulators have been successful in treating this inflammatory skin condition. Tacrolimus also has antifungal properties, which contributes to its therapeutic effectiveness.

Therapy for adolescent SD consists of topical corticosteroids and keratolytic shampoos applied to the scalp. In addition, topical and oral ketoconazole may be used in severe cases. Psoriasiform SD of the scalp is treated as described for cradle cap. Psoriasiform lesions on the face and trunk respond to treatment with topical corticosteroid ointments and emollients. If lesions persist into childhood, then a modified Goeckerman regimen consisting of application of a tar preparation followed by outdoor exposure to sunlight and topical corticosteroids is therapeutic. Generalized erythrodermic SD may require systemic corticosteroids and antibiotics to control superinfection in addition to the antiseborrheic therapies already mentioned. Hospitalization for intravenous antibiotic administration may be required.

In treating infantile SD, the initial use of agents to loosen scale (mineral oil), anti-inflammatory low-potency topical steroid, or antifungal agent is preferred because of the potential toxicity of salicylic acid products by absorption through the skin. If this initial regimen does not work, salicylic acid products or petrolatum should be applied for only 10 minutes and then shampooed out carefully, avoiding the face and particularly the eyes because severe contact irritation may occur. The corticosteroid solution should be applied sparingly and left on for several hours. This regimen may be repeated up to twice daily as needed and then tapered. Heavy metal agents such as selenium sulfide should be reserved for teens and adults, especially because coexisting atopic dermatitis can be an issue for infants and these agents can exacerbate underlying atopic dermatitis. Dramatic improvement usually occurs within 1 week. Lesions occurring on the face, intertriginous areas, and diaper area may be treated with a low-potency topical corticosteroid cream (1% hydrocortisone cream) twice a day. A mid-potency corticosteroid such as 0.1% Kenalog cream may be used on the body twice a day. A midpotency or strong halogenated corticosteroid should not be used on the face, intertriginous areas, or diaper area. Topical ketoconazole (Nizoral), which has been used to treat adult SD, has been found to be beneficial in treating infantile SD. Lesions in the diaper and intertriginous areas may become superinfected with *Candida* species and require topical antifungal creams twice a day in addition to a topical corticosteroid.

## PROGNOSIS

The prognosis for infantile SD is usually excellent. Most cases resolve within the first 6 months of life. Adolescent-onset and HIV-related SD may be more persistent; however, they usually respond readily to topical therapy. Infants who have SD may be at an increased risk for developing atopic dermatitis or psoriasis later.

## TOOLS FOR PRACTICE

### Engaging Patient and Family

## Chapter 327

# SEIZURE DISORDERS

Sarah M. Roddy, MD; Margaret C. McBride, MD

Seizures occur in approximately 1% of all children up to the age of 14 years. The incidence is greatest in the first year of life (approximately 120 cases per 100,000 population) and thereafter the incidence is 40 to 50 cases per 100,000 population until the age of puberty and closer to 10 cases per 100,000 population in the early and mid-teens.

Seizures are caused by abnormal discharges of neurons and may have a wide variety of clinical manifestations. A seizure should be considered a symptom of systemic or central nervous system (CNS) dysfunction. Management consists not only of controlling seizures, but also of diagnosing any potentially treatable underlying condition. Acute conditions associated with seizures include metabolic disturbances, fever, meningitis, encephalitis, and toxic encephalopathy. The terms *seizure disorder* and *epilepsy* are synonymous and are applied to the condition in which a tendency for recurrent, unprovoked seizures exists. Care of children who have epilepsy includes managing the psychosocial effect of epilepsy on the child and family, as well as any associated comorbidities, such as learning disabilities and behavioral problems.

## CLASSIFICATION

Classification of seizures has provided a means to study seizures that have similar pathophysiologic features and to determine which medications are effective for which seizure types. Electroencephalogram (EEG) monitoring aided in the current classification, which is based on characterization of seizure onset and progression. Seizures are either focal or generalized. *Generalized* seizures result from involvement of both cerebral hemispheres simultaneously from the onset of the seizure. Types of generalized seizures include absence, myoclonic, atonic, tonic, clonic, and tonic-clonic seizures. *Focal* seizures, which were called partial seizures in the prior classification, are caused by seizure discharges that begin in 1 hemisphere. Focal seizures are divided further according to the degree of impairment during the seizure and its initial manifestation.

Epilepsy syndromes are also defined in terms of a cluster of signs and symptoms, including seizure type, age of onset, severity, diurnal or nocturnal occurrence, clinical course, associated neurologic dysfunction, inheritance, and EEG findings. Some of the more common generalized epilepsy syndromes include juvenile myoclonic epilepsy, Lennox-Gastaut syndrome, and childhood absence epilepsy. A common focal epilepsy syndrome is benign childhood epilepsy with centrotemporal spikes. Infantile spasms are included in the *epileptic spasms* category because there is inadequate knowledge to make a firm decision regarding whether the spasms should be classified as focal, generalized, or both. As the understanding of the genetics underlying seizure susceptibility and epileptic syndromes evolves, classification will probably change to incorporate that knowledge.

Febrile seizures are considered separately because they are not traditionally diagnosed as a form of epilepsy *unless nonfebrile seizures develop*. Box 327-1 outlines the classification of the various seizure types and some of the epilepsy syndromes.

## Generalized Seizures and Epilepsies

### Generalized Tonic-Clonic Seizures

Generalized tonic-clonic seizures are also known as *grand mal seizures* and consist of motor manifestations and loss of consciousness. The tonic phase is characterized by a sustained contraction of muscles; as a result, the child falls to the ground, usually in opisthotonus. In most instances, extensor posturing

occurs with tonic contraction of the diaphragm and intercostal muscles, which halts respirations and, in turn, produces cyanosis. The tonic phase lasts less than 1 minute and is followed by the clonic phase, which consists of bilateral rhythmic jerking. The jerks may be accompanied by expiratory grunts produced by diaphragmatic contractions against a closed glottis. The frequency of the clonic jerks decreases as the seizure progresses, although the intensity may actually increase. The tongue may be bitten, and bowel and bladder incontinence may occur. The clonic activity usually stops within several minutes. The seizure may be followed by vomiting, confusion, and lethargy, with gradual recovery of consciousness during minutes to hours.

Generalized tonic-clonic seizures may be primary or follow a focal seizure. Primary generalized seizures are usually idiopathic or genetic in origin and are associated with bilaterally synchronous electrical discharges on EEG. Focal seizures may evolve to a bilateral convulsive seizure so rapidly that any suggestion of focal origin by history or EEG is lacking. The EEG may demonstrate a focal discharge that may spread to both hemispheres or may show only bilateral synchronous discharges. The history that is helpful in determining that a seizure is focal in onset is the presence of an aura, head or eye deviation, or focal clonic movement at the onset of the seizure. Neurologic examination may reveal subtle focal signs such as a mild hemiparesis or visual field defect. Complete seizure control is less likely in focal seizures that generalize than in primary generalized seizures.

Effective antiepileptic medications for treating primary generalized tonic-clonic seizures include valproate, lamotrigine, phenobarbital, topiramate, zonisamide, and levetiracetam. Focal seizures that generalize may be effectively treated with these medications, as well as with carbamazepine, oxcarbazepine, and phenytoin.

### Absence Seizures

Absence seizures are generalized, nonconvulsive seizures characterized by interruption of activity, staring, and unresponsiveness; they usually last between 5 and 15 seconds. The episode starts abruptly without warning and ends abruptly with resumption of the child's preictal activity. The child may be unaware that the episode occurred. At times, unresponsiveness is accompanied by eyelid fluttering and upward rotation of the eyes and occasionally by mild clonic movements or automatisms such as lip smacking, grimacing, or swallowing. Seizures may occur more than 100 times per day and may interfere with the child's learning ability. The age of onset is generally between 3 and 8 years; rarely does it occur before 2 years or after 15 years of age. Girls are affected more commonly than boys. The influence of genetic factors in the etiology of absence seizures is suggested by the finding that 15% to 44% of children with absence seizures have first-degree relatives with absence seizures, paroxysmal EEG abnormalities, or both.

The classic finding on the EEG in children who have absence seizures is bilaterally synchronous 3-Hz spike-and-wave discharges. Hyperventilation may be used

### BOX 327-1 Classification of Seizures and Epilepsy Syndromes

#### GENERALIZED SEIZURE TYPES

- Tonic-clonic
- Absence
- Myoclonic
- Clonic
- Tonic
- Atonic

#### GENERALIZED EPILEPSY SYNDROMES

- Lennox-Gastaut syndrome
- Childhood absence epilepsy
- Juvenile myoclonic epilepsy

#### FOCAL SEIZURES TYPES

- Without impairment of consciousness or awareness
- With impairment of consciousness or awareness
- Evolving to a bilateral convulsive seizure

#### FOCAL EPILEPSY SYNDROMES

- Benign childhood epilepsy with centrotemporal spikes
- Epilepsia partialis continua

#### UNKNOWN

- Epileptic spasms

to precipitate the electrical discharge and a clinical seizure. Photoc stimulation during the EEG may also induce the seizure discharge in some children. Generalized tonic-clonic seizures may occur in some children, especially those who have an onset of absence seizures after 8 years of age. The prognosis for remission is good for children with younger age of onset and in whom absence is the sole seizure type, but is less favorable for those who have associated tonic-clonic seizures.

Monotherapy with ethosuximide, valproate, or lamotrigine usually controls absence seizures effectively. Ethosuximide, because of its effectiveness and lower incidence of serious adverse effects, is the drug of choice if the child has only absence seizures. Valproate or lamotrigine are the drugs of choice if associated tonic-clonic seizures exist. Any 2 of these medications may be used together when absence seizures are not completely controlled with 1. Lamotrigine has less deleterious effects on associated problems with attention span than the other 2 drugs. Benzodiazepines also are effective in controlling absence seizures, but their adverse effects on behavior make them second-line therapeutic agents. Phenytoin, phenobarbital, carbamazepine, and oxcarbazepine are usually ineffective for treating absence seizures and may exacerbate them.

### Myoclonic Seizures

Myoclonic seizures are characterized by brief, sudden muscle contractions or jerks that may involve only part of the body or may be generalized. They may occur in clusters, especially when falling asleep or shortly after awakening and, in most instances, no alteration in consciousness is associated with these seizures.

Most drugs that help other primary generalized seizures are helpful for these; however, these may be exacerbated by the medications that are used primarily for focal seizures.

### Clonic Seizures

In clonic seizures, the body part involved contracts and then relaxes, causing a rhythmic jerking. In the contraction phase, the body part or body itself takes on the position caused by the strongest muscles that move that part, which are usually the antigravity muscles—the arm flexors and leg and trunk extensors. If only one side of the body is involved, the body part will be pulled to or activated on that side.

### Tonic Seizures

Tonic seizures are characterized by a sudden sustained contraction of musculature, like the beginning of a tonic-clonic seizure. Sometimes, when these are short, they are hard to distinguish from myoclonic events, which are very short, because the contraction of the muscles involved is not sustained.

### Atonic Seizures

Atonic, or astatic, seizures are also termed *drop attacks*. They are characterized by a sudden decrease in muscle tone, which may result in head nodding or mild leg flexing. More significant decreases in muscle tone may

cause the child to slump to the floor. In most instances, no alteration in consciousness is detectable with these seizures.

Tonic, clonic, myoclonic, and atonic seizures may all be treated by the same medications that are used to treat generalized tonic-clonic seizures.

### Lennox-Gastaut Syndrome

Lennox-Gastaut syndrome is a severe epileptic encephalopathy characterized by focal seizures and a variety of generalized seizures, including tonic, tonic-clonic, and atypical absence seizures, often occurring at a greater frequency than other seizure disorders. Tonic seizures cause sudden, sustained contraction of the muscle groups, at times causing the child to fall. Atypical absence seizures consist of a brief period of staring and immobility. The onset and recovery of atypical absence seizures are less abrupt than those of typical absence seizures. The episodes may be associated with mild tonic motor manifestations, automatisms, or loss of postural tone. Atonic seizures occur and may be preceded by myoclonic jerks. Most of these children begin to have seizures between 3 and 5 years of age; boys are affected slightly more frequently than girls. Many children have neurologic deficits before the onset of Lennox-Gastaut syndrome, including intellectual disability and cerebral palsy, which may be related to hypoxic or other insults to the brain or abnormal brain development. Children may have a history of infantile spasms. The EEG typically shows an irregular, high-voltage, slow (2.5 Hz or slower) spike-wave pattern. The discharges are bilaterally synchronous.

The seizures associated with Lennox-Gastaut syndrome are often very difficult to control. Valproate has been effective in treating the different seizure types and is usually the initial drug of choice. Lamotrigine, topiramate, rufinamide, and felbamate have significantly reduced the frequency of atonic and generalized tonic-clonic seizures. The benzodiazepines, particularly clobazam, have also successfully controlled atonic, myoclonic, and atypical absence seizures. Unfortunately, with increasing doses, the frequency of adverse effects also increases. The development of tolerance is also a problem associated with the use of benzodiazepines. Ethosuximide can help control the atypical absence episodes, and phenytoin can be used for tonic seizures, but sometimes exacerbates the other seizure types involved. The ketogenic diet has been beneficial in seizure control, but because of the nature of the diet, compliance may be a problem. Vagal nerve stimulation has also been beneficial and well tolerated. Some children should be fitted for protective helmets to prevent repeated head injuries with their drop attacks. Generally, the treatment goal is to achieve reasonable seizure control with as few medications as possible to minimize adverse effects. In some instances, the seizures typical of Lennox-Gastaut syndrome occur in otherwise healthy preschool-aged children, associated with normal background and fast polyspike-and-wave changes on EEG. These children have a much better prognosis for seizure control and cognitive development.

### Childhood Absence Epilepsy

Childhood absence epilepsy is the term used for epilepsy that consists only of typical absence seizures with onset before age 8 years. It usually resolves before puberty.

### Juvenile Myoclonic Epilepsy

Juvenile myoclonic epilepsy is a primary generalized epilepsy with an age of onset of 12 to 18 years. It represents 7% of all epilepsy and is characterized by myoclonic jerks that affect mainly the upper extremities and, less commonly, the lower extremities. The jerks usually occur shortly after awakening, and children may complain of clumsiness or difficulty holding objects early in the morning. Approximately 80% of children have generalized tonic-clonic seizures, and 25% have absence seizures in addition to myoclonic seizures. Myoclonic jerks almost always precede the onset of generalized tonic-clonic seizures by months to years. A teenager who has generalized tonic-clonic seizures should be questioned carefully regarding myoclonic jerks. Both the myoclonic jerks and the tonic-clonic seizures may be precipitated by sleep deprivation, stress, alcohol, and hormonal changes. Children remain neurologically normal. Juvenile myoclonic epilepsy is genetic with several different loci identified. The ictal EEG typically shows generalized, symmetrical polyspikes and waves at 4 to 6 Hz. Photoc stimulation precipitates the electrical discharges in some children.

Valproate will control the myoclonic jerks, absence seizures, and generalized tonic-clonic seizures in more than 80% of children, but is often avoided in females of childbearing age. Lamotrigine, topiramate, zonisamide, and levetiracetam are also effective, but phenytoin is not, and carbamazepine and oxcarbazepine may exacerbate the seizures. The rate of seizure recurrence among patients who discontinue therapy during early adulthood is high, but a 25-year follow-up study found that up to 30% may be seizure free or have only morning myoclonic seizures on no medication.

### Focal Seizures

Focal seizures are seizures that originate in a limited area of 1 cerebral hemisphere. The symptoms may be motor, sensory, or cognitive, depending on the location of the neuronal discharge. Motor seizures may be restricted to a part of the body, such as the face or a limb, or they may spread to involve the entire side. They may also spread to the opposite hemisphere, resulting in generalized tonic-clonic seizure activity. Focal tonic-clonic seizure activity may be followed by Todd paralysis, a weakness of the limbs most involved in the seizure. Focal sensory seizures are most often manifested by paresthesias lasting less than 1 to 2 minutes.

Focal seizures may result in impaired consciousness, but, preceding impairment of consciousness, the child may have symptoms that are referred to as the *aura*. Seizure discharges from 1 occipital lobe may cause visual symptoms such as scintillating colored spots or scotoma in the visual field contralateral to the discharge. Seizures with more complex visual hallucinations often progress to altered consciousness.

Auditory seizures are manifested by hearing noises and less commonly by having elaborate, but usually nonverbal, auditory hallucinations such as hearing music. Seizure activity in the olfactory region causes a sensation of an odor, which is usually described as unpleasant. Affective symptoms such as fear or other unpleasant feelings can occur. Anger and rage are extremely rare as seizure manifestations, but may occur during postictal confusion if the child is restrained. *Déjà vu*, the feeling that an experience occurred before, and *jamais vu*, the feeling that a previously experienced sensation is unfamiliar and strange, and a *rising* epigastric sensation are common. Young children have difficulty describing these symptoms and may say only that a “funny feeling” occurred in the head or stomach.

Staring and automatisms, which are involuntary coordinated motor activities, occur when clouding of consciousness occurs. Automatisms include simple phenomena such as chewing, lip smacking, swallowing, and hissing, as well as more complicated activities such as picking at clothes, searching, or ambulating. Automatisms are usually followed by postictal amnesia. The child may become tired and go to sleep.

Focal seizures with impaired consciousness must be distinguished from absence seizures, which are also characterized by staring and unresponsiveness. Episodes of absence seizures have an abrupt onset and termination compared with focal seizures, which have a more gradual onset and termination. Absence seizures last less than 30 seconds and are not associated with postictal confusion. Automatisms can occur if absence episodes are prolonged, but they are often just a continuation of motor activity present before the onset of the seizure.

Focal seizures may evolve into a bilateral or generalized convulsive seizure. When they do, the convulsive or clonic seizure may be asymmetrical. Sometimes focal seizures generalize so quickly that they look like generalized tonic-clonic seizures from the start.

The most frequent EEG finding in focal seizures is an anterior temporal lobe spike discharge, although some children will have spike discharges from other areas. Interictal EEG recordings may be normal. Repeating the EEG increases the likelihood of demonstrating the abnormal discharge. Nasopharyngeal or sphenoidal electrodes rarely add information that is not obtained by scalp recordings that include special temporal placements.

Although focal seizures are caused by focal epileptiform discharges, a focal structural lesion may not be found in most children. Identifiable causes of focal seizures include perinatal insults, head trauma, CNS malformations, encephalitis, and possibly status epilepticus, all of which may be associated with scarring of the temporal lobe. Indolent tumors such as hamartomas and low-grade gliomas can also cause focal seizures and are found in approximately 20% of persons who have intractable focal seizures. Genetic factors play a secondary role in the etiology of focal seizures.

Anticonvulsant drugs used in the treatment of focal seizures include carbamazepine, oxcarbazepine, and valproate. These and most of the newer anticonvulsant medications are used preferentially to phenytoin

and phenobarbital. Carbamazepine and oxcarbazepine are the drugs of choice in children because of their efficacy and relatively mild adverse effects. If seizures are not controlled with carbamazepine, then the addition of acetazolamide may result in improved seizure control. For some children, oxcarbazepine is less sedating. Children who have medically intractable focal seizures should be evaluated at a comprehensive epilepsy center to determine their candidacy for surgical intervention, which results in complete seizure control in up to 90% of children.

### **Benign Childhood Epilepsy With Centrotemporal Spikes**

Benign childhood epilepsy with centrotemporal spikes is also known as *rolandic epilepsy*, *sylvian seizures*, and *centrotemporal epilepsy*. This epilepsy syndrome is a common type of focal motor epilepsy in childhood. The onset is usually between 5 and 8 years of age. Boys are more often affected than girls. Genetic factors play a role in the etiology. The seizures typically occur during sleep, although children may occasionally have episodes during wakefulness. Episodes are characterized by the child awakening with 1 side of the face twitching. The oropharyngeal muscles are also often involved, causing the child to make unintelligible gurgling sounds. The ipsilateral upper extremity may be involved, but only rarely is the lower extremity involved. In rare cases, a seizure episode will become generalized. Consciousness is often retained during the seizure, although the child may not be able to speak. Most seizure episodes last less than 2 minutes. The frequency of seizures is low, with 25% of children having a single-seizure episode and 50% having fewer than 5 episodes. The typical EEG findings are midtemporal or centrotemporal spike discharges occurring unilaterally or independently bilaterally in light sleep and sometimes induced by hyperventilation. Neuroradiologic studies show no abnormalities to correlate with the EEG focus. If a child has infrequent episodes, then no treatment may be needed. If the episodes frighten the child and a decision is made to initiate treatment, then carbamazepine or oxcarbazepine are the drugs of choice, although most anticonvulsants are effective. Some children with rolandic epilepsy are also prone to absence seizures, and carbamazepine and oxcarbazepine may exacerbate the absences. The focal seizures remit when the child is approximately 9 to 12 years of age, but no later than 17 years of age. Remission is long lasting, and no developmental or neurologic impairment is usually associated with these seizures other than some increased incidence of attention deficit or possibly some minor learning difficulties.

### **Epilepsia Partialis Continua**

Epilepsia partialis continua is a rare type of seizure in which twitching is continuous and limited to 1 side of the body. The twitching frequently involves only a few muscles and occurs most often in the hand or foot. Consciousness is preserved, but the seizure activity may weaken the extremity involved. Seizure activity may persist for hours to months. Focal encephalitis and tumor have been associated with this type of

seizure. Most anticonvulsants have some efficacy, but medical control of epilepsia partialis continua is generally difficult to achieve.

### **Unknown Seizures**

#### **Epileptic Spasms**

**INFANTILE SPASMS (WEST SYNDROME).** Infantile spasms are the most common type of “epileptic spasms” and a unique form of epilepsy, with onset during the first year of life. The seizures are characterized by a sudden contraction of neck, trunk, and extremity muscles. The spasms may be flexor, extensor, or mixed flexor-extensor and last only a few seconds each, but they often occur in clusters of up to 100 individual spasms. A typical episode is characterized by dropping of the head along with abduction of the shoulders and flexion of the lower extremities. The infant may cry during or after the spasm. Pallor, flushing, grimacing, laughter, and nystagmus are observed during some episodes. Episodes are common on awakening from sleep, during drowsiness, and with feedings, but are rare during sleep. The peak age of infantile spasm onset is between 3 and 7 months, with an estimated incidence of 0.24 to 0.60 per 1,000 infants. Boys are more likely to be affected than girls.

Infantile spasms are usually divided into symptomatic and cryptogenic groups based on the presence of a predisposing etiologic factor. Included among symptomatic infantile spasms are those associated with abnormal neurologic development before the onset of spasms. Causes include structural abnormalities of the brain, hypoxic-ischemic insults, CNS infections or hemorrhages, and inborn errors of metabolism. Children who have tuberous sclerosis account for up to 25% of patients who have symptomatic infantile spasms. The cryptogenic group are infantile spasms for which no etiologic factor can be found. Cryptogenic infantile spasms tend to start later than the symptomatic spasms.

The EEG pattern associated with infantile spasms is known as *hypsarrhythmia* and is characterized by high-voltage slow waves with irregularly interspersed multifocal spike-and-sharp waves. Hypsarrhythmia may precede the onset of clinical manifestations, or it may occur later or not at all. Over time, the hypsarrhythmia usually evolves into other focal or generalized abnormalities; in some cases, the EEG may normalize.

Infantile spasms are resistant to treatment with most anticonvulsants. The treatment used most commonly in the cryptogenic Adrenocorticotrophic hormone ACTH in a long-acting form is administered as a single daily intramuscular dose of 20 to 40 IU. Adrenocorticotrophic hormone is expensive, and studies of oral corticosteroids suggest that they may be an effective and less expensive alternative. Adverse effects of ACTH and steroids are significant and include Cushing syndrome, hypertension, susceptibility to infections, hyperglycemia, gastrointestinal bleeding, and electrolyte disturbance. In the symptomatic group, alternative anticonvulsants may be tried before ACTH. Vigabatrin is the only anticonvulsant other than ACTH with clear efficacy and is the drug of choice for infantile spasms caused by

tuberous sclerosis. There are reports, but not good evidence, for the benzodiazepines, particularly nitrazepam, topiramate, zonisamide, and valproic acid, sometimes controlling infantile spasms.

The prognosis for infants who have infantile spasms remains grave. The average mortality rate is approximately 20%, with aspiration pneumonia related to severe developmental abnormalities being a common cause of death. Approximately 80% of survivors are intellectually disabled. The spasms usually remit by a few years of age, but 55% to 60% of children subsequently develop other forms of seizures. The prognosis is more favorable for infants whose neurologic development was normal before the onset of the spasms.

### Neonatal Seizures

Seizures are the most common manifestation of neonatal neurologic disease and occur in approximately 0.5% of all newborns. Neonatal seizures may be generalized or focal and are classified using the same criteria as in children. For a long time, seizures have been identified only clinically, but as EEG has become more available to intensive care nurseries, it has been recognized that acute injury of the neonatal brain results in frequent subclinical electrographic seizures that can only be recognized with an EEG. In fact, only 10% or less of electrographic seizures in the neonate may be recognized clinically, particularly after initiating antiseizure medication. Additionally, the traditional antiseizure medications that are available for newborns in parenteral forms (phenobarbital, phenytoin, and lorazepam), and even the newer medication levetiracetam, are not effective in completely controlling these electrographic seizures, which tend to last several days after the injury. Genuine debate exists about whether seizures in the neonate can further the brain damage that caused them, although more recent evidence suggests that seizures worsen neurodevelopmental outcome. Uniformity of opinion is lacking about how aggressive to be in treating subtle neonatal seizures and those which seem to have no clinical correlate, but more recent studies suggest detrimental effects of seizures in neonates. Therefore, most clinicians try to eliminate both electroclinical and electrographic-only seizures, especially when they are the shorter-term seizures related to asphyxia or infection, if that can be done without serious side effects.

The combination of clinical manifestations of neonatal seizures and their likelihood of being associated with simultaneous electrographic seizures has led to revised classifications of seizures in the neonate. The clinical manifestations are classified as follows:

1. Subtle seizures occur in both full-term and premature infants and are often overlooked. These seizures consist of eye deviation, blinking, sucking, swimming movements of the arms, pedaling movements of the legs, and apnea. Electroencephalogram recordings do not always show correlation of electrical seizure discharges with the clinical seizure activity. This finding has raised the possibility that, in some instances, the abnormal movements arise from regions of the brain from which abnormal electrical activity cannot be detected with surface

electrodes or that they may not be seizures. Subtle seizures usually occur in infants who have severe CNS insults.

2. Clonic seizures are either focal or multifocal. Focal clonic seizures are characterized by rhythmic jerking that remains localized and is almost always associated with electrographic seizure discharges from the central part of the opposite hemisphere. Although focal clonic seizures can result from focal CNS lesions such as cerebral infarction, they can also occur with metabolic disturbances. Multifocal clonic seizures are characterized by clonic activity in 1 extremity that migrates randomly and often rapidly from side to side and place to place within the body. The EEG shows multifocal independent areas of electrical discharge. Clonic seizures should be differentiated from benign neonatal sleep myoclonus, which consists of small-amplitude clonic activity that may wax and wane in various parts of the body. The movements of benign neonatal sleep myoclonus occur in healthy term neonates and infants only during sleep and are accompanied by a normal EEG throughout the jerking period. This disorder is self-limited and not associated with later epilepsy.
3. Tonic seizures are focal or generalized. Focal tonic seizures are characterized by sustained posturing of a limb or asymmetrical posturing of the neck and trunk and possibly accompanying subtle seizure activity such as eye deviation. Generalized tonic seizures are characterized by tonic extension of the limbs. Less commonly, the upper extremities are flexed and the lower extremities are extended. They often have no electrographic correlate and may be some kind of brainstem phenomenon rather than seizures. They are usually associated with severe EEG background abnormalities. In premature infants, they may occur at the onset of severe intraventricular bleeding.
4. Myoclonic seizures are flexion jerks of the upper or lower extremities. They may occur singly or in a series of repetitive jerks, and they are sometimes associated with tonic spasms and multifocal seizures. The EEGs in infants with myoclonic seizures are usually abnormal. They may show a burst suppression pattern, although the EEG may not change during the myoclonic event. Infants with myoclonic seizures tend to have severely abnormal dysgenetic brains or metabolic defects. Occasionally, the seizures are cryptogenic. Infants with these seizures may later develop infantile spasms. These myoclonic seizures should be differentiated from benign myoclonic jerks that occur during sleep in neonates and are accompanied by a normal EEG. Jitteriness is a movement in neonates that may be confused with seizure activity. The movement is a tremor that is stimulus sensitive and can be stopped by passively flexing the affected limb. Jitteriness is not associated with ocular phenomena.

Some investigators advocate the identification of neonatal seizures by EEG recording, maintaining that only electrical seizures are true seizures and require treatment. However, this theory remains controversial because identical clinical seizures in the same infant

may, at times, not be associated with electrical seizures. Clearly, however, electrical seizures may not have clinical correlates; hence, EEG recording should be done for all infants at risk for seizures to identify these clinically silent electrical seizures.

When managing neonatal seizures, the physician must rapidly pursue the treatable causes, such as hypoglycemia, electrolyte imbalance, and infection, as well as EEG confirmation of seizure activity to help avoid the pitfall of treating coarse jitteriness or other transient abnormal movements with antiseizure medication. Treating the seizures themselves is urgent if they interfere with vital functions such as maintaining good arterial oxygen saturation. An approach to treating neonatal seizures is outlined in Box 327-2.

The prognosis of neonatal seizures relates to the underlying diseases that caused them. Intellectual disability and cerebral palsy are more common sequelae than seizures. Infants who have seizures related to hypoxic-ischemic encephalopathy, hypoglycemia, or bacterial meningitis have a 50% chance of developing normally; those whose seizures result from late-onset hypocalcemia and primary subarachnoid hemorrhage have a greater than 90% chance of developing normally. The interictal EEG is helpful in determining the prognosis. A normal background EEG pattern is usually associated with a good neurologic outcome; a markedly abnormal background pattern, such as burst suppression or marked suppression of voltage, is associated with a high risk for neurologic sequelae.

### Febrile Seizures

Febrile seizures are seizures that occur in young children who have fever, but no evidence of intracranial infection or acute neurologic illness. Simple febrile seizures are generalized tonic-clonic convulsions that

last less than 15 minutes and do not recur within 24 hours. Complex febrile seizures are less common and are focal or prolonged beyond 15 minutes or recur within 24 hours. Febrile seizures occur in children between 3 months and 5 years of age; the median age of occurrence is 18 to 22 months. Approximately 2% to 5% of children will experience a febrile convulsion; boys are more susceptible than girls. Familial clustering of febrile seizures occurs, and mutations of the *SCN1A* gene have been found in some families.

A febrile seizure may be the first sign that a child is ill. Whether the seizure activity is triggered by the rapid rise of fever or the actual height of the temperature is unknown. Febrile seizures can be triggered by any illness that causes fever, most frequently by otitis media and upper respiratory tract infections. The rate of febrile seizures with shigellosis, salmonellosis, and roseola is high, possibly related to a direct effect the causative organism has on the CNS or to a neurotoxin they produce.

One-third of children who have a febrile seizure will have another seizure with another febrile illness. The younger the child is at the time of the first episode, the greater the risk for recurrence. Approximately 50% of the recurrences occur within 6 months of the initial seizure; 75% occur within 1 year.

Usually, seizure activity stops by the time the child is evaluated. However, if the seizure continues, then lorazepam should be administered (see Chapter 374, Status Epilepticus). The temperature should be brought down by using rectal antipyretics, removing blankets and clothing, and sponging. After seizure activity is controlled, evaluation is directed toward finding the cause of the fever. If the child is younger than 1 year of age, or if the child has not rapidly returned to normal, then a lumbar puncture should be strongly considered to evaluate for meningitis.

### BOX 327-2 An Approach to the Treatment of Neonatal Seizures

- Ensure adequate ventilation and perfusion.
- Make an immediate determination of blood glucose and obtain blood for laboratory testing of glucose, calcium, magnesium, and electrolyte studies.
- Correct any associated metabolic abnormality.
- Hypoglycemia: If glucose level is low (<40 mg/dL), immediately give 10% dextrose intravenously in a dose of 2 mL/kg. Maintain blood glucose levels between 40 and 80 mg/dL by continuous intravenous infusion and monitor the levels in both full-term and premature infants. Try to avoid significant hyperglycemia.
- Hypocalcemia: Correct by administering 5% calcium gluconate solution, 4 mL/kg, intravenously at a rate of 1 mL/min to maintain serum calcium levels above 7 mg/dL while monitoring cardiac rate and rhythm.
- Hypomagnesemia: Correct serum magnesium levels to 1 mmol/L with 50% magnesium sulfate solution, 0.2 mL/kg, intramuscularly.
- Continued seizure activity requires consideration of other etiologies and administration of anticonvulsants.
- Phenobarbital is given in a loading dose of 20 mg/kg intravenously over 10 minutes. Additional doses of 5 or 10 mg/kg can be given, up to a total of 40 mg/kg.
- Fosphenytoin is given intravenously in a loading dose of 20 mg/kg of phenytoin equivalents while monitoring cardiac rhythm.
- Levetiracetam as 20 to 50 mg/kg has been used and is currently being assessed in a multicenter study.
- Lorazepam can be given in doses of 0.1 mg/kg intravenously for persistent seizures. Respiratory status should be monitored.

From Weiner SP, Painter MJ, Geva D, Guthrie RD, Scher MS. Neonatal seizures: electroclinical dissociation. *Pediatr Neurol.* 1991;7(5):363–368; Lawrence R, Inder T. Neonatal status epilepticus. *Semin Pediatr Neurol.* 2010;17(3):163–168; and Maytal J, Novak GP, King KC. Lorazepam in the treatment of refractory neonatal seizures. *J Child Neurol.* 1991;6(4):319–323.

The EEG is generally not helpful in evaluating children who have simple febrile seizures. Electroencephalogram tracings recorded within 1 week of the seizure often show posterior slowing. Paroxysmal activity is seen in the EEGs of 35% to 45% of children who are followed for several years. These EEG abnormalities do not predict recurrence of febrile seizures or the development of epilepsy. In children with focal febrile seizures, an EEG may indicate focal epileptiform abnormalities, which would be associated with an increased chance of recurrence and of epilepsy.

Treatment of febrile seizures includes family education that addresses the benign nature of the seizures, the use of antipyretics, and first aid for seizures. Oral diazepam (0.33 mg/kg body weight administered every 8 hours during febrile illness) reduces the risk for recurrent febrile seizures in that illness, but also sedates the child. No studies have demonstrated that antipyretics reduce the recurrence risk for simple febrile seizures. Administering phenobarbital at the onset of a febrile illness does not prevent seizure activity because therapeutic blood levels are not achieved soon enough. Prophylactic treatment with anticonvulsant agents may be considered if neurologic development is abnormal or if it is a complex febrile seizure. Administering phenobarbital in doses that achieve blood levels of 15 mcg/mL reduces the recurrence of febrile seizures. Valproate also seems to be effective in prophylaxis; phenytoin and carbamazepine do not prevent recurrences. The adverse effects of anticonvulsant therapy must be weighed against the possible benefits. No evidence has been found that prophylactic treatment reduces the risk for subsequent epilepsy.

The risk for subsequent epilepsy in children who have febrile seizures is less than 5%. Factors associated with subsequent development of afebrile focal seizures include focal febrile seizures, prolonged seizures, and repeated episodes of seizures with the same febrile illness. Factors associated with development of afebrile, generalized seizures include more than 3 febrile seizures, a family history of afebrile seizures, and age older than 3 years at the time of the first febrile seizure.

### **Paroxysmal Nonepileptic Events**

Paroxysmal nonepileptic events (PNEs) are also called pseudoseizures, nonepileptic seizures, and sometimes stress seizures. They are a form of conversion reaction and are typically associated with some kind of secondary gain related to sources of stress or anxiety. They must be recognized if inappropriate treatment is to be prevented. They differ from epileptic seizures in several respects. The movements are usually not clonic, but may be quivering or random thrashing. Usually, no incontinence, injury, or tongue biting is associated with PNEs. Episodes may be dramatic, with screaming, shouting, and thrashing of the extremities. Episodes also may vary greatly in the same child. Usually, no postictal period occurs. Paroxysmal nonepileptic events can occur in early childhood, but are more frequent in adolescence, especially in girls. They may occur in children who also have epileptic seizures. A detailed history and observation of an episode may be

all that is needed to diagnose these events. A prolactin level drawn within 10 to 20 minutes of an event may help differentiate it from an epileptic seizure. Usually a prolactin level drawn soon after a PNE remains normal, whereas after a generalized tonic-clonic seizure or a focal seizure with loss of awareness, the level is twice normal or higher. Capturing the event during video EEG monitoring establishes the diagnosis in children in whom the distinction cannot be made clinically because no epileptic discharges occur during the event. Treatment is directed toward the psychosocial issues involved.

## **ETIOLOGY**

### **Neonatal Seizures**

Neonatal seizures have multiple origins; however, only a few causes account for most cases. Determining the cause of neonatal seizures is important because specific treatment may be indicated. The cause of the seizures is also an important factor influencing prognosis. Some of the most common causes of neonatal seizures are described as follows:

1. Hypoxia-ischemia is the most common cause of seizures in both premature and full-term infants. These seizures usually begin within the first 24 hours of life and may be difficult to control for several days. Metabolic disturbances in the infant also may complicate seizure control. Infants with hypoxia-ischemia who are treated with head or body cooling may have seizures after 3 days during rewarming.
2. Intracranial hemorrhage is another cause of seizures in both premature and full-term infants. Intraventricular hemorrhage is seen mainly in premature infants within the first 3 days of life. Generalized tonic seizures may be associated with severe hemorrhage involving the brain parenchyma. Infants who have a primary subarachnoid hemorrhage may not have any clinical symptoms or may develop seizures on the second day of life. These infants often are full term and normal neurologically except for their seizures. Subdural hemorrhage is associated with trauma and may be associated with focal seizure activity.
3. Metabolic disturbances, especially hypoglycemia and hypocalcemia, are also associated with seizures in neonates. Infants who are small for gestational age, post-term infants, and infants of diabetic mothers are at risk for hypoglycemia, and the blood glucose level should be monitored closely. Low-birth-weight infants and infants of diabetic mothers are also at risk for hypocalcemic seizures, which may occur when calcium levels decrease below 7 mg/dL during the first 2 to 3 days of life. In many instances, infants who have hypocalcemia also have a history of hypoxia, which contributes to the risk for seizure. Hypocalcemic seizures that occur later are usually related to a low-calcium and high-phosphate intake in non-breastfed infants. Late hypocalcemic seizures are now rare as a result of the development of formula that has an appropriate ratio of calcium and phosphorus supplementation. Other metabolic disturbances less frequently associated with seizures in neonates include hyponatremia,

hypernatremia, local anesthetic intoxication, pyridoxine deficiency or dependence, and a variety of inborn errors of metabolism, some of which are associated with hyperammonemia and some of which may be ameliorated by dietary restrictions or supplementations. A helpful overview of the inborn errors of metabolism associated with epilepsy and often presenting in infancy was written by Papetti and colleagues.

4. Infection, including bacterial and viral intracranial infections, is an important cause of neonatal seizures. The most common bacterial causes are group B streptococci and *Escherichia coli*. Onset of seizures with meningitis is usually after the first 3 to 4 days of life. Prenatal nonbacterial infections causing neonatal seizures include toxoplasmosis, rubella, herpes simplex virus, coxsackievirus type B, and cytomegalovirus.
5. Malformations of the brain can cause seizures at any time during the newborn period. The malformations associated most commonly with seizures are those that have cortical dysgenesis such as lissencephaly, pachygyria, and polymicrogyria.

### Childhood Seizures

In most children with seizures, if an underlying cause is going to be identifiable, then the child's history or physical examination will provide clues. Whereas in most neonates a cause is identifiable (see section on Neonatal Seizures), in older children and adolescents a cause is identifiable in less than 20%, and if a child has no abnormalities by history or examination at the time of onset of seizures, then a cause is rarely identified. The more abnormal the child's neurodevelopmental status, the more likely a cause will be identified or may already have been determined before the onset of seizures. These causes include brain malformations, genetic disorders, disorders of metabolism, traumatic or previous infectious injury of the brain, and neoplasm. Children with infantile spasms and Lennox-Gastaut syndrome are more likely to have an identifiable cause. Idiopathic generalized epilepsies such as childhood absence epilepsy and juvenile myoclonic epilepsy are more likely to be related to genetic factors.

### Genetic Factors in Childhood Epilepsy

Family histories and twin studies clearly show that genetic factors play a role in some children with epilepsy. Additionally, the fact that some genetic syndromes such as Angelman syndrome and Rett syndrome predispose a child to seizures raises interest in the role of different genes in the susceptibility to seizures. Genes have been identified that govern the formation of the subunits of potassium and sodium channels and of the  $\gamma$ -aminobutyric acid type A and acetylcholine receptors in nerve cell membranes. Aberrations in these genes lead to increased excitability of nerve cell membranes. Benign familial neonatal and infantile convulsions have been linked to potassium channel subunit genes *KCNQ2* and *KCNQ3* and to the *SCN2A* gene, which governs the  $\alpha 2$  subunit of the neuronal sodium channel. Other genes have been identified in a group of familial epilepsies called *generalized*

*epilepsy with febrile seizures plus*. The epilepsies within these families include a range of severity from recurrent febrile seizures to multiple seizure types, including absence, myoclonic, and atonic seizures, and even focal seizures of temporal lobe origin. The most commonly found genetic abnormalities in these families are mutations of the *SCN1A* gene. Even without a family history of epilepsy, especially if a child has seizures combined with dysmorphic features and significant global developmental delay, an underlying genetic abnormality may be found in 25% by targeted gene sequencing panels and a few of these may have specific treatments.

In families with identifiable mutations of 1 gene, the severity of the epilepsy may vary, suggesting that other genes modify the expression of their primary genetic abnormality. Probably a significant number of yet-to-be-identified genes play a direct or indirect role in the excitability of the nerve cell membrane and together define each individual's seizure threshold that is then modified by environmental factors. A helpful overview of the current knowledge of genetic factors in epilepsy was written by Thomas and Berkovic.

## DIFFERENTIAL DIAGNOSIS

The first step in evaluating the child who has a seizure is making the correct diagnosis. Seizures must be differentiated from other paroxysmal disorders in childhood such as syncope, breath-holding spells, staring related to inattention, paroxysmal vertigo, cardiac arrhythmias, and stereotypic behaviors (see Chapter 179, Nonconvulsive Periodic Disorders). Additionally, the type of seizure should be identified to decide what diagnostic tests to pursue and which medication to use when treatment is indicated.

## EVALUATION

### Laboratory Evaluation

Laboratory tests usually performed at the time of the initial seizure include measuring serum electrolytes, calcium, magnesium, and blood glucose. In some cases, the history or examination may indicate that a more extensive laboratory evaluation is required.

### Electroencephalography

The EEG, which measures the physiologic function of the brain, changes throughout childhood, reflecting brain maturation. The EEG is important in evaluating a child who has seizures because it helps define the seizure type. An epileptiform EEG may support the diagnosis of epilepsy, but a normal tracing does not exclude the diagnosis. Other abnormalities, such as slowing and background disorganization, are much less specific. Repeat tracings increase the likelihood of detecting epileptiform discharges in patients who have seizures. Procedures such as hyperventilation, photic stimulation, and sleep should be used when obtaining EEG recordings. Nasopharyngeal and sphenoidal electrodes are now rarely used to detect mesial temporal discharges because they rarely add information to that obtainable by special scalp electrode placements. Video EEG monitoring is useful in correlating clinical symptoms with electrical seizure activity

and may be useful when clinical manifestations are atypical or pseudoseizures are in question. Although the EEG provides electrophysiologic evidence to support the diagnosis of epilepsy, EEG abnormalities must be interpreted in view of the clinical symptoms. Some individuals have epileptiform discharges and other EEG abnormalities without ever having a clinical seizure; anticonvulsant treatment is not indicated for such individuals. The 2 most common epileptiform abnormalities seen in children who have not had a seizure are centrottemporal spikes and 3-Hz spike and wave complexes in drowsiness or light sleep.

### Neuroimaging Studies

Plain radiographs of the skull can detect calcifications that may be seen in some syndromes, but they rarely help in evaluating children who have epilepsy. Computed tomography (CT) and magnetic resonance imaging (MRI) detect structural abnormalities such as changes in myelination, heterotopic gray matter, and low-grade tumors. Magnetic resonance imaging is more sensitive than CT and, therefore, the better study when available. Although it requires sedation in younger children, it is not associated with any risk from irradiation and provides much greater detail. Neuroimaging studies are not warranted in every child who has epilepsy; however, an MRI should be performed in children who have focal neurologic abnormalities on examination or intractable epilepsy. Positron emission tomographic and single-photon emission CT scans are useful in localizing metabolic alterations with seizure activity and seizure foci, but their clinical relevance is only in individuals with intractable epilepsy being evaluated for epilepsy surgery.

### Lumbar Puncture

The cerebrospinal fluid should be examined in children in whom meningitis or encephalitis is suspected. In other children, the lumbar puncture may be helpful in diagnosing disorders of glucose transport or of neurotransmitters.

### Genetic Studies

In some children with unexplained epilepsy, particularly those with other neurodevelopmental or dysmorphic features, it may be important to test for specific genetic disorders. Typically, a geneticist or child neurologist would help with such an evaluation. Several companies offer gene panel testing for the more common genetic causes of epilepsy, and these panels are constantly updated as new genes are identified. (See Genetic Factors in Childhood Epilepsy.) Looking for these disorders will be increasingly important as the gene products are understood and more specific therapies become available.

### Screening for Associated Learning and Behavioral Problems

Children with epilepsy and without global cognitive disability tend to have more learning problems, especially reading problems and attention deficit, than children without epilepsy. Additionally, behavioral problems may be identified in up to 50% of children with epilepsy, and this number may increase with the

added adverse effects of medication and the burden of a chronic disorder. Hence, determining whether these comorbidities exist through history, school records, behavioral checklists, or any combination is essential so that they may also be addressed to improve the overall quality of life of the child with epilepsy.

## MANAGEMENT

### Seizures in Neonates

After clinical seizures are controlled, electrographic seizures may continue and, if frequent or prolonged, may merit further anticonvulsant therapy. In general, seizures related to acute injuries, such as asphyxia, stroke, or acute CNS infections other than herpes, are self-limited and stop after several days, although they may recur months or years later. Although many physicians continue seizure prophylaxis after neonatal seizures for several months or longer, no evidence has been found that continuing treatment past the neonatal period will change the chance of recurrence. Therefore, seizures caused by acute injuries are usually treated short term and, in some nurseries, infants are not sent home on anticonvulsants if their seizures stopped or, if they are, then anticonvulsants are continued for only a few weeks. Because phenobarbital has a long half-life, especially in asphyxiated infants, it will remain at good levels after a full loading dose for several days, and no maintenance therapy may be needed. Seizures related to brain malformations or inborn errors of metabolism may be much more persistent, and the duration of treatment will depend on the infant's clinical course.

### Seizures in Children Beyond the Neonatal Period

The risk for seizure recurrence is important when deciding whether to initiate antiepileptic therapy. Some types of seizures, such as absence, myoclonic, akinetic, and infantile spasms, have a recurrence rate of virtually 100% and usually recur by the time the primary care physician sees the child. These types of seizures require treatment. However, children who have a generalized tonic-clonic or focal seizure have a recurrence risk of approximately 40%. Factors that increase the risk for recurrence include a focal seizure with impaired consciousness, an abnormal neurologic examination, and focal epileptiform abnormalities on the EEG. The best prognosis is in children who have a generalized seizure, normal neurologic examination, and a non-epileptiform EEG. Most children who have a single seizure should be observed for recurrence, but should not be given antiepileptic medication. More than 50% of the recurrences occur within 6 months, up to 69% within 1 year, and 88% within 2 years. If a second seizure occurs, then initiating antiepileptic medication should be considered because approximately 80% of children who have a second seizure will have more.

After the child has recurrent seizures and antiepileptic medication is indicated, the primary care physician is faced with the decision of which medication to prescribe. Diagnosing seizure type correctly is the critical first step in treatment because some seizure

disorders respond to certain medications and may be exacerbated by others. With the increasing understanding of gene aberrations that predispose individuals to epilepsy and the growing field of pharmacogenetics, the hope of being able to choose the best medication at the best dose for a particular individual with epilepsy may soon be realized. Meanwhile, in choosing among potentially effective antiepileptic agents for the specific individual's seizures, the drug that has the least adverse effects should be selected. The medication is given at a dose that will result in a low therapeutic blood level. The dose should be increased until seizures are controlled or adverse effects are prominent. If the initial medication is not fully effective, then a second medication may be added. Consider discontinuing use of the first medication if seizures are fully controlled with the second medication. Striving for monotherapy is important, if possible, given that polytherapy often does not improve seizure control, but may significantly increase toxicity. Closely monitoring for the potential cognitive and behavioral adverse effects of the antiepileptic medications is essential.

When devising an optimal dosing regimen, primary care physicians should consider the pharmacokinetics of the various antiepileptic medications. The dosing frequency is determined by the *half-life*, defined as the time in which the serum level decreases to 50% of the initial value. The dosing interval should be no longer than the half-life of the medication, which means that most antiepileptic agents may be administered twice a day and some only once a day. The efficacy of an antiepileptic medication should be evaluated only after 5 half-lives elapse because this period is required for the medication to reach a steady state. In antiepileptic medications that induce hepatic enzymes (eg, phenobarbital, phenytoin, carbamazepine, oxcarbazepine), the half-life decreases during the first weeks of treatment. If breakthrough seizures occur at times of low (trough) serum drug levels, toxic effects occur at times of peak drug levels, or children require higher antiepileptic medication levels, then the total daily dose should be divided into more frequent doses.

Serum drug levels can guide the dose adjustment of some antiepileptic medications. A baseline level may be obtained when the child has been taking an appropriate dose long enough to have stable levels. Other indications for obtaining levels include verifying compliance, breakthrough seizures, and toxic effects. Levels may also be checked when other medications are added or deleted from the child's regimen. The timing of the sample in relation to the last dose is important for interpreting the levels, especially in drugs with short half-lives.

### Specific Antiepileptic Medications

In the past 25 years, multiple new anticonvulsant drugs were approved for use in the United States. These drugs include felbamate (1993), gabapentin (1994), lamotrigine (1995), topiramate (1996), tiagabine (1997), levetiracetam (1999), oxcarbazepine (2000), zonisamide (2000), pregabalin (2006), lacosamide (2008), rufinamide (2008), vigabatrin (2009), and clobazam (2011). All of these drugs, except rufinamide

and clobazam, were originally tested and approved in the United States as add-on therapy for focal seizures. Most underwent trials with additional seizure types and in younger children after their original approval, and some received additional US Food and Drug Administration (FDA)-approved indications, or evidence exists for wider use than their current FDA-approved indications. Lamotrigine, topiramate, zonisamide, and levetiracetam have demonstrated efficacy in primary generalized seizures. These newer anticonvulsants, except for gabapentin and tiagabine, which have been generally less effective than the others, are more widely used than many of the older agents because of their better side-effect profiles. Pregabalin is approved for adjunctive therapy in individuals older than 18 years of age; data are limited on its use in children.

Table 327-1 outlines commonly used antiepileptic medications and their properties. (Medications used to abort seizures are discussed in Chapter 374, Status Epilepticus.) The reported half-life in some cases takes into account the half-life of active metabolites. Therapeutic blood levels are those reported in children at a steady state whose seizures were controlled or improved with minimal side effects. These levels are not well established for some of the newer anticonvulsants and, in many cases, the reported range in patients who responded to typical doses is large, decreasing the utility of drug monitoring. Because there are varying sensitivities to the side effects of these medications, some individuals will have side effects at levels that others easily tolerate. The most common and more serious side effects are indicated. Most side effects are dose related, but drug rashes, especially Stevens-Johnson syndrome, and hepatic reactions are usually not dose related.

### Acetazolamide

Acetazolamide is an inhibitor of the enzyme carbonic anhydrase. It is an effective adjunctive treatment of several types of seizures, although its antiepileptic properties are not well understood. Acetazolamide can be used in combination with valproic acid for treating absence, myoclonic, and akinetic seizures. Adding acetazolamide to carbamazepine may improve control of focal seizures. Acetazolamide metabolism is not affected significantly by other medications.

### Carbamazepine

Although carbamazepine is one of the older medications, it is still used because it has relatively few effects on cognitive function. It may also affect behavior positively. The most serious adverse effect associated with carbamazepine is aplastic anemia. This effect is extremely rare, occurring at a rate of less than 1 case per 200,000 treatment years. A complete blood cell count should be obtained before carbamazepine therapy is initiated and should be repeated after 2 to 3 weeks. Whether further blood cell counts are useful when the initial counts are normal is unclear, but they should be obtained more readily when the child is ill and are often repeated biannually or annually. Neutropenia as low as 3,000/mm may occur, especially in association with a viral infection, but does not predict

**Table 327-1** Common Antiepileptic Medications

DRUG	INDICATIONS	HALF-LIFE (HR)	USUAL DAILY DOSE (mg/kg)	THERAPEUTIC LEVELS (mcg/mL)	ADVERSE EFFECTS
Acetazolamide	Absence, myoclonic, akinetic, focal	10–12	10–20	10–14	Diuresis, paresthesias, sedation, carbon dioxide retention, rashes
Carbamazepine	Focal, focal evolving to bilateral convulsive	18–55, initially 3–23 on chronic therapy	2–5 initially, 5–25	4–12	Allergic rashes, nausea, diplopia, blurry vision, dizziness, hypersensitivity, hepatitis, aplastic anemia
Clobazam	Lennox-Gastaut syndrome in children $\geq 2$ years of age	12, active metabolites 40	0.1–0.2 initially, 0.6–1.0 maximum	100–300	Sedation/somnolence, increased secretions
Clonazepam	Absence, primary generalized, infantile spasms	20–36	0.01–0.2	0.01–0.07	Sedation, hyperactivity, inattention, aggressiveness, tolerance, ataxia, withdrawal seizures
Ethosuximide	Absence, myoclonic, akinetic	15–68	15–40	40–100	Nausea, abdominal discomfort, hiccups, drowsiness, behavioral problems, dystonias, myelosuppression, drug-induced lupus
Felbamate	Focal (in patients $> 12$ years of age), Lennox-Gastaut syndrome	20 (in monotherapy)	15–45 (maximum 3,600 mg)	30–100	Anorexia, weight loss, nausea, insomnia, headache, fatigue, aplastic anemia
Gabapentin	Focal, focal evolving to bilateral convulsive in patients $> 12$ years of age	5–7	Total daily dose 900–1,800 mg (maximum 3,600 mg)	2–20	Somnolence, dizziness, ataxia, fatigue
Lacosamide	Focal in patients $> 17$ years of age	13	Start 50 mg bid, increase 50 mg every week; top dose is 400 mg daily	5–16	Nausea, vomiting, dizziness, increased PR interval
Lamotrigine	Focal, primary generalized, absence, atypical absence, atonic, myoclonic	7–45	Initially 0.15 if on valproate, 0.6 if on an enzyme-inducing drug, and 0.3 if on both or neither of valproate and an enzyme-inducing drug. Double the dose in 2 weeks and continue slow titration over 2–3 months to target dose	2–14	Rash, including Stevens-Johnson syndrome, vomiting
Levetiracetam	Focal, focal evolving to bilateral convulsive, myoclonic, primary generalized tonic-clonic	6–8	Start at 10–20 mg/kg/day, increase every 2 weeks; top dose 60 mg/kg or 3,000 mg	6–35	Somnolence, irritability, hostility
Oxcarbazepine	Focal, focal evolving to bilateral convulsive	4–9	10–50: start at 10 mg/kg; top dose 2,400 mg divided into 2 daily doses	15–35	Somnolence, nausea, dizziness, rash, hyponatremia

Table 327-1

## Common Antiepileptic Medications—cont'd

DRUG	INDICATIONS	HALF-LIFE (HR)	USUAL DAILY DOSE (mg/kg)	THERAPEUTIC LEVELS (mcg/mL)	ADVERSE EFFECTS
Phenobarbital	Neonatal, febrile, focal, focal evolving to bilateral convulsive, primary generalized, akinetic	36–120	3–5 (<25 kg), 2–3 (25–50 kg), 1–2 (>50 kg)	10–40	Sedation, inattention, hyperactivity, irritability, cognitive impairment, rare hypersensitivity reactions
Phenytoin	Focal, focal evolving to bilateral convulsive, generalized tonic-clonic	7–42 (nonlinear kinetics)	5–7	10–20 (or lower)	Rashes, hirsutism, gingival hyperplasia, coarse features, psychomotor slowing, neuropathy, folate deficiency, myelosuppression, drug-induced lupus
Rufinamide	Lennox-Gastaut syndrome	6–10	Start 10 mg/kg divided into 2 daily doses, increase by 10 mg/kg every other day; top dose of 45 mg/kg or 3,200 mg	15–30	Somnolence, fatigue, dizziness, headache, nausea, shortened QT interval
Tiagabine	Focal	3–9	Start at 0.1 up to 0.25–1.5 (maximum 30 mg)	40–100	Dizziness, somnolence, headache, depression
Topiramate	Focal, primary generalized, tonic, atonic, atypical absence, infantile spasms	20–30	1–9	2–20	Somnolence, anorexia, fatigue, difficulty with concentration, nervousness, kidney stones, oligohidrosis
Valproic acid	Primary generalized, absence, myoclonic, akinetic, febrile, infantile spasms, Lennox-Gastaut syndrome, focal infantile spasms	6–16	10–30, monotherapy, may need more in polytherapy	50–100 (150 if tolerated)	Nausea, tremor, weight gain, hair loss, thrombocytopenia, hepatic failure, pancreatitis
Vigabatrin	Infantile spasms	5.7 in infants to 7.5 in adults	Start 50 mg/kg divided into 2 daily doses, increase by 50 mg/kg per week; top dose of 150 to 200 mg/kg	0.8–36	Visual field loss, irritability
Zonisamide	Focal, primary generalized, infantile spasms	24–60	Start at 1–2 mg/kg and may work up to 10 mg/kg; top adult dose is 600 mg	10–40	Somnolence, dizziness, kidney stones, oligohidrosis

more serious myelosuppression. The dose of carbamazepine may need to be changed during treatment because the drug tends to induce its own metabolic breakdown. Phenobarbital, phenytoin, and clonazepam decrease carbamazepine serum levels.

### **Clobazam**

Clobazam is approved for add-on therapy in Lennox-Gastaut syndrome in children 2 years of age and older. It is converted by subclasses of the cytochrome P-450 enzymes to an active metabolite, desmethylclobazam, which has about half the efficacy, but is present in about 10 times the concentration. Desmethylclobazam and its metabolites are excreted in urine. Although the half-life of clobazam is 12 hours, the half-life of this active metabolite is 40 to 50 hours. It is best to start clobazam at a low dose (5 mg/day in children <30 kg and 10 mg/day in bigger children) and increase it at 1- to 2-week intervals because of the sedation associated with it. The maximum dose suggested for children under 30 kg is 20 mg a day, whereas up to twice that may be used in bigger children. Caution is particularly important when adding it to other sedating medication. The dose should be modified when used with felbamate, selective serotonin reuptake inhibitors, omeprazole, and oxcarbazepine because these drugs may tend to increase its levels and the levels of its active metabolites. Its metabolism and that of its active metabolite are markedly slowed in individuals with deficits in the cytochrome P450 enzyme system. When clobazam is stopped, it requires tapering over several weeks or even months if the child has been taking it for more than a few weeks. It may have less associated tachyphylaxis than other benzodiazepines, and the associated sedation and increased secretions are less than with clonazepam.

### **Clonazepam**

Clonazepam, a benzodiazepine, is not a first-line anti-epileptic medication because of its adverse effects. It causes significant behavioral changes, including hyperactivity, decreased attention span, aggressiveness, and restlessness. It also causes increased secretions, which may be a problem in children with reactive airways or cerebral palsy and associated compromised swallowing mechanisms; it also may lead to swallowing dysfunction in higher levels. Additionally, similar to all of the other benzodiazepines, its efficacy is relatively short term because of tachyphylaxis. Because withdrawal of the drug may cause irritability, myoclonus, and increased seizures, it should be withdrawn slowly. Treatment with clonazepam is usually reserved for myoclonic seizures that are refractory to other medications.

### **Other Benzodiazepines**

Clorazepate is the least sedating of the benzodiazepines and is sometimes used adjunctively for resistant seizures. Diazepam and lorazepam may also be used. However, all of the benzodiazepines are associated with tachyphylaxis and some sedation and withdrawal seizures. Sometimes rotating from one to another helps this class of medications retain its efficacy. Their most significant place in epilepsy is in intermittent use,

as in status epilepticus, for which intravenous lorazepam is the drug of choice (see Chapter 374, Status Epilepticus.) The rectal preparation of diazepam may be administered safely during a prolonged seizure outside the hospital setting. Intranasal or intrabuccal midazolam as 0.2 mg/kg has been shown to act faster than rectal diazepam and is growing in acceptance as an alternative for use outside of the hospital in children with prolonged seizures. These drugs may also be used to stop flurries of seizures in patients predisposed to them or sometimes for nocturnal seizures.

### **Ethosuximide**

Ethosuximide has a limited spectrum of efficacy; it is used mainly for treating absence seizures and some forms of myoclonic seizures. Behavioral disturbances can occur in some children taking ethosuximide, and pancytopenia has been associated with long-term administration. Therefore, periodic blood cell counts may be necessary. Ethosuximide does not interact significantly with other antiepileptic medications.

### **Felbamate**

Felbamate was approved by the FDA in 1993 for treatment of focal seizures in adults and for adjunctive therapy in children who have Lennox-Gastaut syndrome. The most common adverse effects of felbamate are anorexia, weight loss, nausea, insomnia, headache, and fatigue. No serious cardiac effects have been reported. A year after felbamate was approved and widely used because of its lack of associated sedation, more than 20 cases of aplastic anemia among persons taking felbamate were reported. The incidence of, and predisposing factors to, this problem have not been fully determined. Its use decreased significantly after these reports and the associated warning. No cases have been reported in children younger than 13 years of age. A few cases of hepatic toxicity have also been reported. Currently, felbamate should only be used in children whose epilepsy does not respond to other drugs appropriate to the seizure type, and in whom the potential benefits of treatment outweighs the low risk for aplastic anemia. Felbamate interacts with phenytoin, carbamazepine, and valproate; therefore, doses of these medications must be reduced by 25% to 50% when felbamate is added. Felbamate levels are lowered by medications that induce liver enzymes; consequently, felbamate doses may need to be increased.

### **Gabapentin**

Gabapentin is approved as adjunctive therapy for focal seizures and focal seizures evolving to bilateral convulsive seizures in patients 3 years of age and older. Although gabapentin treatment has been shown to significantly reduce seizure frequency among children refractory to conventional anticonvulsants, it has not proved to be as effective an anticonvulsant as most other agents and is currently used more for neuropathic pain than for seizure control. One advantage of gabapentin is that it does not interact with other drugs. Additionally, it has few drug interactions and is 100% excreted renally, offering an advantage to children with liver failure. In add-on trials, the most

common adverse effects were somnolence, dizziness, ataxia, and fatigue.

### **Lacosamide**

Lacosamide is approved as adjunctive therapy of focal seizures in individuals 17 years of age and older. There are no significant interactions with other antiepileptic drugs, but lacosamide may potentiate generalized seizures.

### **Lamotrigine**

Lamotrigine is approved for treatment of focal seizures in individuals older than 16 years of age and as add-on therapy in children 2 years of age and older with Lennox-Gastaut syndrome. Studies in children reveal that lamotrigine reduces the frequency of both focal and generalized seizures. It was particularly effective in patients with absence, atypical absence, and atonic seizures. Its main advantage is its overall alerting effect. The most common adverse effects of lamotrigine are rash and vomiting. The rash is usually maculopapular or morbilliform, but a few cases of Stevens-Johnson syndrome have occurred. Co-medication with valproic acid increases the incidence of rash. Starting a low dose of lamotrigine and slowly increasing the dose throughout 10 to 12 weeks helps minimize the risk for rash. Lamotrigine administration has no effect on the metabolism of other antiepileptic drugs; however, phenobarbital, phenytoin, and carbamazepine decrease the half-life of lamotrigine. Valproic acid increases the half-life of lamotrigine by 2- or 3-fold; therefore, doses of lamotrigine should be lower when given in combination with valproic acid. Recommended starting doses are 0.15 mg/kg when used in combination with valproate, 0.3 mg/kg when used with either both valproate and an enzyme-inducing drug or neither of these, and 0.6 mg/kg when used with an enzyme-inducing drug, but not valproate. The starting dose is doubled after 2 weeks and tripled after another 2 weeks, and then the doses may be increased in larger increments, still taking 2 to 3 months to get to target dose. The range of therapeutic plasma concentrations is wide (1 to  $\geq 14$  mcg/mL), making monitoring of serum levels less useful. Side effects may not be seen with levels as high as 16 to 18 mcg/mL.

### **Levetiracetam**

Levetiracetam is approved as adjunctive therapy for focal seizures in children 4 years of age and older, for myoclonic seizures in children 12 years of age and older, and for primary generalized tonic-clonic seizures in children 6 years of age and older. Adverse effects include somnolence, behavior problems, and nervousness. The irritability that may be associated with levetiracetam can be improved by taking 50 to 100 mg a day of pyridoxine. The lack of significant adverse effects and drug interactions has made levetiracetam an initial choice, especially for primary generalized seizures.

### **Oxcarbazepine**

Oxcarbazepine is approved for initial monotherapy and adjunctive therapy for focal seizures in children

2 years of age and older. It is well tolerated with generally fewer adverse effects and especially less sedation than most other anticonvulsants. Infrequent dose-related adverse effects include somnolence, dizziness, diplopia, nausea, and vomiting. More serious, but infrequent, adverse events include rash and hyponatremia. An advantage over many drugs is its lack of drug interactions. Studies comparing oxcarbazepine with phenytoin and carbamazepine indicated similar efficacy, but lower rates of discontinuation because of adverse effects, and a study comparing it with valproate indicated similar efficacy and rates of discontinuation because of adverse effects. Oxcarbazepine is rapidly becoming a drug of first choice for focal seizures. It has been shown to be well tolerated in infants and young children. Oxcarbazepine is a moderate liver enzyme inducer.

### **Phenobarbital**

Phenobarbital is one of the oldest antiepileptic agents still in use. Because of its long half-life, it has the advantage of requiring dosing only once or twice a day. The dose per kilogram decreases as body weight increases. Failure to decrease the per-kilogram dose levels in older children will result in toxic levels. Because phenobarbital is a relatively safe medication in terms of serious toxic effects, monitoring parameters other than serum levels is not necessary. The major disadvantage of phenobarbital is its effect on behavior and cognitive function, including hyperactivity, irritability, and attention deficits. Because of these side effects, phenobarbital is used mainly in young infants, whereas some of the other drugs are used first in toddlers and school-aged children. Maintaining serum levels at the minimum level for seizure control may help decrease these adverse effects. Phenobarbital administration will lower the serum levels of carbamazepine and valproate. Administering valproate will increase phenobarbital levels; therefore, phenobarbital doses should be decreased by 25% to 50% to prevent toxic effects when prescribed concomitantly with valproate.

### **Phenytoin (Fosphenytoin)**

Phenytoin is also an older antiepileptic medication that was used widely in the past. It is used infrequently now for long-term therapy because alternatives with fewer adverse effects and more steady pharmacokinetics are available. Phenytoin has zero-order kinetics, causing blood levels to vary significantly with small changes in dose. Therefore, changes in dose should be monitored by serum levels, and only small dose changes should be made when serum levels are close to or within the therapeutic range. Phenytoin is commonly used for treating status epilepticus because intravenous administration results in rapid penetration into the CNS. Fosphenytoin is a water-soluble pro-drug of phenytoin with a more neutral pH and less tissue irritation. It can be administered intravenously or intramuscularly, whereas phenytoin may not be used intramuscularly. Although phenytoin is an effective antiepileptic agent in generalized tonic-clonic and focal seizures, its adverse effects limit its use. Cosmetic adverse effects include gingival hypertrophy,

hirsutism, and coarsening of the facial features. Also of concern are its effects on mood and cognitive function, which include depressed mood, slowed psychomotor functioning, and, in a few patients, depressed IQ scores. Other adverse effects include folate-deficiency anemia, cerebellar degeneration, and allergic dermatitis, including Stevens-Johnson syndrome. Valproic acid may lower total serum phenytoin levels, but the free phenytoin level transiently increases and then returns to its original level; thus, no adjustment in dose is necessary. Phenytoin may decrease carbamazepine levels and increase phenobarbital levels. Because it is highly protein bound and, with other protein-bound medications, it is displaced from protein, free levels are sometimes useful, and the therapeutic range for free phenytoin is 1 to 2 mcg/mL.

### Rufinamide

Rufinamide is approved as adjunctive therapy of Lennox-Gastaut syndrome in children 4 years of age and older. Adverse effects include somnolence, dizziness, headache, and nausea. Rufinamide can cause dose-dependent shortened QT interval and is contraindicated in children who have familial short QT interval. It has minimal effects on other antiepileptic drug levels, but can lower carbamazepine and lamotrigine levels and increase phenobarbital and phenytoin levels. Phenytoin, phenobarbital, and carbamazepine all decrease the plasma concentration of rufinamide, and valproate increases its level.

### Tiagabine

Tiagabine is approved for adjunctive therapy of focal seizures in adults and children 12 years of age and older. Its efficacy in generalized seizures is unclear. Adverse effects include dizziness, somnolence, and headache. Tiagabine does not alter the concentrations of other antiepileptic drugs except for a slight decrease in valproate levels. Enzyme inducers such as carbamazepine, phenytoin, and phenobarbital lower tiagabine levels. Tiagabine is used only infrequently for seizure control in children because other anticonvulsants are more effective.

### Topiramate

Topiramate is approved as initial monotherapy for focal seizures and primary generalized tonic-clonic seizures in children 10 years of age and older and for adjunctive therapy in children 2 years of age and older for focal and primary generalized tonic-clonic seizures and for Lennox-Gastaut syndrome. Topiramate has also been effective for treating infantile spasms in some children. The most common adverse effects of topiramate are somnolence, anorexia, fatigue, difficulty with concentration and nervousness, and oligohidrosis. It may be associated with a metabolic acidosis. It also increases the chances of kidney stones and is rarely associated with open-angle glaucoma. Topiramate administration has minimal effects on the metabolism of other antiepileptic drugs. However, concomitant therapy with phenytoin or carbamazepine will lower topiramate levels. Topiramate is also now used for mood disorders and headache prevention.

### Valproic Acid

Valproic acid has a broad spectrum of efficacy and also has the advantage of minimal cognitive adverse effects. Tremor may occur with high serum levels. Other dose-related adverse effects include increased appetite, weight gain, reversible hair loss, nausea and vomiting, and thrombocytopenia. Rarely, fatal hepatotoxicity has been associated with valproic acid. Most cases occur during the first 3 months of treatment. Those at greatest risk for hepatotoxicity are children younger than 2 years of age who receive valproic acid as part of antiepileptic polytherapy. Children younger than 2 years of age and those who develop hyperammonemia without liver failure are generally supplemented with L-carnitine, although this supplementation does not necessarily prevent the serious liver toxic effects. Valproic acid should be administered extremely cautiously to children who have preexisting hepatic dysfunction. Liver function should be monitored in children taking valproic acid, especially those in the high-risk group. Valproic acid raises the level of phenobarbital; therefore, the dose of phenobarbital must be decreased by 25% to 50% if valproic acid is added. Carbamazepine, phenobarbital, and phenytoin decrease valproic acid serum levels.

### Vigabatrin

Vigabatrin is approved as adjunctive therapy in adults with medically refractory focal seizures with impaired consciousness and in children 1 month to 2 years of age with infantile spasms. It may be particularly effective in infantile spasms related to tuberous sclerosis. Its use has been associated with irreversible peripheral visual field loss. There is increased risk in males, with longer length of treatment, and with higher cumulative vigabatrin dose. Another adverse effect is white matter vacuolation and intramyelinic edema. The MRI changes are seen in infants rather than adults and seem to be transient and asymptomatic. The long-term clinical significance of these changes is unknown.

### Zonisamide

Zonisamide is approved as adjunctive therapy in adults with focal seizures. Few studies have evaluated its use in children in the United States. However, in Japan, where it has been available longer, zonisamide is used widely in children with both focal and primary generalized epilepsy and infantile spasms. Adverse effects of zonisamide include somnolence, anorexia, dizziness, kidney stones, oligohidrosis, and rash. An advantage of zonisamide is its half-life of 24 to 60 hours, allowing once-a-day dosing.

## Other Treatments for Seizures

### Ketogenic Diet

In some children, the ketogenic diet has proved to be an effective alternative treatment, with one-half of children with intractable epilepsy showing a 50% decrease in seizure frequency and some being seizure free at 1 year. The benefits of fasting as a treatment for seizures were reported years ago, but the diet was not consistently used. Its popularity has waxed and waned since

its introduction in the 1960s. A multicenter prospective study on the efficacy of the ketogenic diet in children with intractable epilepsy found that 10% of treated children were seizure free at 1 year. A greater than 50% decrease in seizure frequency occurred in an additional 50% of the children. Seizure type, patient age, and EEG abnormalities were not related to outcome.

The exact mechanism by which the diet controls seizures is unknown, although ketone body formation is critical for the diet to be effective. To achieve ketosis, the child is given a high-fat, adequate protein, low-carbohydrate diet, sometimes with calorie restriction. Carbohydrate restriction is so crucial that sometimes medication forms that the child is receiving or may be prescribed must be without any added dextrose, effectively eliminating liquid forms. Dextrose in intravenous fluids should be minimized. The child is usually admitted to the hospital to initiate the diet, which allows monitoring for hypoglycemia and other complications such as intolerance of the high-fat content. Before and during the hospitalization, the dietitian teaches the parents about the diet, giving them sample menus and explaining how to measure foods. The first 24 hours of fasting to initiate the diet is no longer adhered to. Strict adherence to the diet is needed for it to be successful. Complications of the diet include constipation, renal stones, fatigue, and metabolic acidosis. Initiating and monitoring the ketogenic diet requires a multidisciplinary team, including the nutritionist/dietitian, pharmacologist, nurse, social worker, and any others that can help communicate with the school and encourage the family and child to adhere to the diet.

### **Vagal Nerve Stimulation**

Vagal nerve stimulation, a treatment for intractable epilepsy, emerged during the late 1980s and the 1990s. The first vagal nerve stimulation device was implanted into a human in 1988. Several studies report the use of vagal nerve stimulation in children, including children as young as 1 year of age; however, it is approved only in children as young as 4 years of age. Most studies report approximately 50% improvement of seizure frequency in one-half of the children, with a few becoming seizure free. Children selected for vagal nerve stimulation had seizures that were intractable to medical treatment or unacceptable adverse effects from medication. Some children continued to have seizures despite having epilepsy surgery. Positive effects seemed to be maintained over several years of follow-up.

Vagal nerve stimulation is associated with alertness, a benefit to many children with intractable epilepsy who often experience sedation from their anticonvulsant therapy. It may also have antidepressant effects. Adverse effects associated with vagal nerve stimulation are generally uncommon and include infection, hoarseness, neck pain, insomnia, and, occasionally, emergence of behavioral abnormalities, which may be related to increasing alertness. Improvements in language function have been noted in some children.

The vagal nerve stimulation device is surgically implanted subcutaneously in the anterior chest wall, usually just under the clavicle, and stimulates the left

vagus nerve. The mechanism for the antiepileptic effect of vagal nerve stimulation is not known, but changes in cerebrospinal fluid amino acids and activation of the noradrenergic system in the locus coeruleus occur with the stimulation.

### **Psychosocial Issues**

Treating the child with a seizure disorder must also address psychosocial issues. Parents and children may have many fears and need reassurance. The terms *epilepsy* and *seizure disorder* must be explained, and parents need to understand that the diagnosis of epilepsy does not mean that their child is intellectually disabled or has a psychiatric disorder. Guidelines should be given on what to do when a child has a seizure, including positioning on the side and putting nothing in the mouth. Witnessing a seizure can be frightening. Parents may be afraid that the child is going to die and should be told that death from a seizure is rare. Helpful pamphlets are available from the Epilepsy Foundation of America, and some parents appreciate the information available in several books for families of children with epilepsy. The Web sites for the Epilepsy Foundation of America ([www.epilepsyfoundation.org](http://www.epilepsyfoundation.org)) and the American Epilepsy Society ([www.aesnet.org](http://www.aesnet.org)) are also helpful sources of information. Many larger communities have local chapters of the American Epilepsy Society or independent epilepsy associations that provide education and support for individuals and families.

Activities of children with seizures should be restricted as little as possible. A child with a seizure disorder should not swim alone or go bike riding without a helmet. However, these rules apply to all children, whether or not they have epilepsy. Children with epilepsy should take showers rather than baths as soon as they are old enough and should not be allowed to bathe unattended. Contact sports are permissible when epilepsy is controlled. The decision about climbing up to certain heights should be based on how well the child's seizures are controlled. Parents need encouragement to treat the child normally and not be overprotective.

### **Discontinuation of Antiepileptic Therapy**

After seizures are controlled for a period of 2 years, consideration should be given to discontinuing antiepileptic medications. Studies show that approximately 75% of children who were seizure free for longer than 2 years remained seizure free after antiepileptic medications were discontinued. The EEG can be helpful when considering discontinuing antiepileptic medications. In children who have idiopathic epilepsy and a normal EEG, the prognosis for remaining seizure free after discontinuing medications is good, except in juvenile myoclonic epilepsy (discussed earlier). However, if the EEG demonstrates slowing, the risk for seizure recurrence is higher. The risk for recurrence is not increased if medication is tapered over a period as short as 6 weeks versus a longer taper. Long-term follow-up of children after withdrawal of medication has shown that 50% of the recurrences occur within 6 months and 60% to 80% within 2 years.

### Intractable Seizures

When seizures continue despite anticonvulsant therapy, 3 possibilities should be considered before deciding that the child's seizures are intractable to anticonvulsant therapy.

1. Seizures may be occurring at times when the child has lower blood levels of medication because of incomplete compliance or because dosing intervals are too long.
2. The medication may not be appropriate for the child's type of seizures. Primary generalized seizures will often not respond and may even worsen if treated with medications that are indicated for focal seizures (eg, carbamazepine, phenytoin). Any medication may worsen seizures in some individuals, sometimes because of associated drowsiness, but, in many instances, the reason is not understood.
3. The child's repeated events may represent 1 of the non-epileptiform paroxysmal disorders rather than an electrical seizure. Pseudoseizures can be especially difficult to differentiate from seizures because they tend to occur in persons who have epilepsy.

If a child is having epileptic seizures and the seizures continue despite appropriate amounts of the correct medications, then the child has intractable seizures. Approximately 15% of children who have epilepsy have intractable seizures, and approximately 50% of these children may be appropriate candidates for epilepsy surgery. Therefore, children who have intractable seizures should be referred to a center that has a multidisciplinary team of professionals, including epileptologists, specialized neurosurgeons, neurophysiologists, neuropsychologists, neuroradiologists, psychologists, and family therapists. These professionals as a team can best determine the location of the epileptic zone within the child's brain and the potential morbidity from loss of function in that area or adjacent tissue, can perform the surgery, and can treat the secondary effects of the surgery on the child and the family. Although epilepsy surgery can be performed at any age, it is best performed soon after intractability of seizures is established. If a long period of recurrent intractable seizures can be avoided, some of the secondary physiologic and psychosocial effects of growing up with epilepsy may be prevented, and children are more likely to live up to their potential in adult life.

Epilepsy surgery consists either of resecting the epileptic focus, such as a temporal lobectomy, a cortical resection, or a hemispherectomy, or of disconnecting the pathways that may facilitate the spread of epileptic activity within the brain, such as a corpus callosotomy and multiple subpial transections.

The outcome from temporal lobectomies in appropriately chosen children is as good as in adults—65% or more become seizure free, and another 15% are significantly improved; morbidity is minimal. Hemispherectomies in children who have a congenital hemiparesis and resistant seizures originating in the damaged hemisphere result in control of seizures in 75% of cases and often improved function because the normal, opposite hemisphere is no longer being

interrupted by spreading seizure discharges. A few cases of intractable infantile spasms associated with focal brain disturbances may also benefit from lesionectomies or partial or complete hemispherectomies. Corpus callosotomy is a palliative procedure for individuals who do not qualify for a local resection. It can be effective in controlling drop attacks and the resultant injuries in children who have multiple seizure types. Results are best in higher-functioning individuals who have localized CNS dysfunction as opposed to diffuse CNS dysfunction. Multiple subpial transections may be done for children whose epilepsy arises from essential parts of the cortex, which cannot be removed without significant morbidity.

### WHEN TO REFER

- Type of seizure is unclear.
- The need to treat, the choice of medication, or the dose of medication is unclear.
- Seizures are refractory to medication.
- Infantile spasms are suspected—a reason for an urgent consult.

### WHEN TO ADMIT

- Seizures are acutely uncontrolled or prolonged.
- Video EEG monitoring is needed.
- Rapid changes in anticonvulsant doses are needed, resulting in a risk for marked increase in seizures.
- Ketogenic diet is initiated.

**Chapter 328****SEPTIC ARTHRITIS**

Stephanie Yee-Guardino, DO; Johanna Goldfarb, MD

**DEFINITION OF TERMS**

Pyogenic, or septic, arthritis refers to a bacterial infection of the joint space. Other forms of arthritis include reactive or postinfectious arthritis (an immunologically induced inflammatory response to a distant infection) and the arthritis associated with rheumatologic disorders (eg, juvenile idiopathic arthritis [JIA]). These latter forms of arthritis are aseptically in that no pathogens are found in the joint space or fluid. Pyogenic arthritis most commonly affects young children and infants, but it can occur at any age. Pyogenic arthritis constitutes a clinical emergency because complications of untreated infection include dissolution of

articular cartilage, necrosis of the underlying epiphysis, destruction of the adjacent growth plate, and dislocation of the joint itself. Complications can be minimized by prompt diagnosis and appropriate treatment. A high index of suspicion is necessary to avoid missing a case of septic arthritis.

**PATHOPHYSIOLOGY**

Hematogenous seeding of the synovial membrane is the most common cause of bacterial arthritis in children. Infection also can occur by contiguous spread from an adjoining osteomyelitis or by direct inoculation of bacteria into the joint after a either penetrating wound, intra-articular injection, or joint surgery. (For a more complete discussion, see Chapter 304, Osteomyelitis.) The spread of bacteria from a bone infection into a joint occurs most often in infancy. Transphyseal blood vessels in the very young child allow early spread of bacteria from the metaphysis of the bone across the growth plate to the epiphysis and into the joint cavity. In infants, therefore, infections that begin in the bone often spread quickly into the joint and often manifest as joint symptoms. This manifestation must be considered when evaluating a young child with localized pain, especially involving the femur or hip.

The organism most commonly responsible for septic arthritis across all age groups is *Staphylococcus aureus*. In neonates, Gram-negative organisms, coagulase-negative staphylococci, and *Streptococcus agalactiae* (group B) also cause pyogenic arthritis. In older infants and young children, *Haemophilus influenzae* type b was once a common pathogen, but vaccination against this organism has made it extremely rare as a cause of bacterial infection in children. After *S aureus*, group A *Streptococcus* is the next most common cause of septic arthritis in children older than 5 years. In children younger than 5 years, *Kingella kingae* is an unusual cause of septic arthritis that requires special attention for successful culture. First described in Israel, this organism has been identified with increasing frequency in the United States. Monoarticular gonococcal arthritis can occur after genital infection with *Neisseria gonorrhoeae*. In a sexually active teenager who has monoarticular arthritis of a large joint, evaluation should include gonococcus as a possible cause. Evaluation for genital gonococcal infection and other sexually transmitted infections should be part of the initial evaluation. The organism can be isolated from the joint and genital sites but requires attention to culture technique and prompt plating in the microbiology laboratory on media appropriate for its growth. This infection can follow, and is distinct from, the reactive arthritis involving multiple joints of disseminated gonococcal disease. Gonococcal septic arthritis is a result of hematogenous seeding of the joint and can follow the bacteremia of untreated disseminated gonococcal disease. The bacteremic illness associated with *N gonorrhoeae* causes a reactive (sterile or aseptic) arthritis involving multiple joints and a vesicular rash. Similar to *N gonorrhoeae*, *N meningitidis* also can cause a reactive arthritis. Multiple joints are involved; but unlike with gonococcus, this arthritis occurs after recovery from the acute infection, following treatment of meningitis or meningococcemia with antimicrobial

therapy. This reactive arthritis resolves spontaneously over time and requires only symptomatic therapy.

The consequences of bacterial arthritis can be severe. In addition to the direct destructive effects of the infection, the host's inflammatory response can add to the damage. By raising intra-articular pressure, intra-capsular infection can obstruct blood flow, leading to necrosis of the epiphysis and the underlying growth plate. Finally, an untreated joint infection can result in joint instability through destruction of the ligamentous fibers of the capsule. These factors are of special concern for the hip joint in children.

Considering the possible consequences and, particularly in the young child, the potential for permanent deformity and disability, the need for accurate diagnosis and expeditious treatment of septic arthritis cannot be overstressed.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis of pyogenic arthritis includes the other forms of arthritis, reactive and rheumatologic or inflammatory, and, on occasion, leukemia. Reactive and inflammatory arthritis often involve multiple joints, whereas pyogenic arthritis almost always involves a single joint. Transient synovitis, which most often affects the hip in young children, is often preceded by a recent history of upper respiratory infection, pharyngitis, otitis media, or gastroenteritis. Fever is rare in these cases. Legg-Calvé-Perthes disease must be considered when hip pain is involved. Although children with infective arthritis are often very ill from an associated bacteremia, rheumatologic disease is usually more subacute or chronic. A reactive arthritis often follows a prior obvious infection, such as the polyarthritis that can follow meningococcal infections; this history helps guide the diagnosis. The pattern of inflammatory arthritis is sometimes helpful in making the diagnosis, as in the case of the occurrence of multiple and alternating joint involvement in arthritis associated with rheumatic fever. JIA is a diagnosis of exclusion, and can be confused with septic arthritis. When children with JIA have high fever and a single joint is involved, the diagnosis can be more confusing. In many instances, the diagnosis is made only with time when fevers persist, other joints become involved, or the single joint fails to have a pathogen isolated and fails to respond to therapy for a pyogenic infection. The diagnosis of JIA can remain unclear for weeks to months until the course clarifies the chronicity of the disease (see Chapter 324, Rheumatologic Diseases). At times, both JIA and a bacterial infection of the bones and joints can be confused with leukemia. Children with leukemia may present with bone pain, with or without fever. The bone pain of leukemia can cause a limp or other non-specific signs and can be confused with a septic joint, osteomyelitis, or JIA. Examining the bone marrow is often required to confirm the diagnosis. The laboratory tests that support a diagnosis of pyogenic arthritis can help point the evaluation in the proper direction. A child with leukemia may have anemia, low white blood cell count (see Chapter 285, Leukemias), or low platelet count. If not present at first, these signs will occur over time.

Some bacterial pathogens that cause arthritis are more difficult to identify, such as *Mycobacterium tuberculosis* or *Borrelia burgdorferi*. A history of exposure to tuberculosis or the occurrence of infection in the summer in an endemic area for Lyme disease will help direct the evaluation (see Chapter 287, Lyme Disease). These pathogens are identified by special testing, which may be prompted by abnormalities in the fluid aspirates. In both these conditions, the fluid does not grow a common pathogen on routine cultures in spite of fluid analysis that is suggestive of bacterial infection. For example, evaluation of a child for possible tuberculosis includes culturing the joint fluid for *Mycobacterium* on special media, placing a tuberculin skin test, and ordering a chest radiograph to look for signs of primary infection. The child with possible Lyme disease will often have a history of the rash of erythema migrans; serologic testing can help confirm the diagnosis. Knowing the frequency of these unusual pathogens in the pediatrician's area of practice is crucial in guiding the evaluation of a child with presumed bacterial arthritis.

Referred pain from an adjacent joint that is infected can also complicate presentation. At times, septic arthritis causing decreased movement at a joint can be confused with an isolated neuropathy. Additionally, septic arthritis of the shoulder can cause a brachial plexus neuropathy, and septic arthritis of the hip can cause neuropathies of the femoral and sciatic nerves. These diagnoses, occurring without infection, should not be associated with pain or fever.

## EVALUATION

### Clinical History

Signs of acute illness most often accompany the onset of septic arthritis. The onset of fever, malaise, poor appetite, irritability, and localized symptoms and signs is usually acute. In septic arthritis, as in osteomyelitis, the neonate presents a unique challenge because systemic signs may be less apparent. However, localized signs are usually prominent, particularly pain with motion of the involved joint. The failure of a child to move an infected joint should suggest this diagnosis. When septic arthritis is present, passive movement of the affected extremity almost invariably elicits severe pain. Limp may also be a presenting complaint.

### Physical Findings

Swelling, erythema, tenderness, and redness of the skin over the joint are usually present, but are difficult to detect in a deep joint such as the hip. The most characteristic finding is pain with joint motion. When a lower extremity joint is involved, the child usually refuses to bear weight or limps. Manipulation of the hip joint, such as with diaper changes, causes significant pain. This pain is often the first sign to a parent or nurse caring for the child that a problem exists. Limited range of motion of an infected upper extremity joint may result in concerns about a neurologic problem, a *pseudoparalysis*. Although older children and teenagers are usually able to localize pain, the physician should remember that pain can be referred to an unaffected joint. Joints of the lower extremities are the

most common sites of septic arthritis, with the knee the most affected joint. Rarely, and usually with prolonged bacteremia, more than 1 joint can become infected.

Some characteristic signs help suggest the diagnosis. To decrease pain, the child will usually hold an infected joint very still. The joint is held immobile by muscle spasm in a position that maximizes capsular volume, thus minimizing the intra-articular pressure. For the hip, the preferred position is a combination of moderate flexion, abduction, and external rotation; for the knee, gentle flexion; and for the shoulder, adduction against the trunk. For a child to seem entirely well and in no distress is not unusual, so long as the affected joint is allowed to remain undisturbed. If a child holds a joint still and has a fever, then the diagnosis of septic arthritis is assumed.

### Laboratory Testing

Laboratory results can be helpful in supporting the diagnosis of septic arthritis. The erythrocyte sedimentation rate is typically elevated, though it may be normal early in the course of infection. The C-reactive protein is also increased, and it is a more sensitive test during the initial illness because it rises earlier than the sedimentation rate. Both the sedimentation rate and C-reactive protein are useful in following the patient's response to treatment following diagnosis. Blood cultures should always be obtained because most pyogenic arthritis cases in children are of hematogenous origin. Blood cultures are positive in at least 40% of children with septic arthritis. Other testing may include titres for Lyme, *Streptococcus*, and other pathogens. In some cases, a TB test by serum interferon may be appropriate, such as in the older child in whom tuberculosis is being considered as a cause. Procalcitonin has been studied as a specific marker in differentiating acute osteomyelitis and septic arthritis from viral and noninfectious inflammatory bone and joint conditions and may be a useful test in the future.

Joint fluid in pyogenic arthritis is generally cloudy or purulent, with a leukocyte count of more than 50,000 cells/mcL, and has a predominance of polymorphonuclear cells. Although the fluid of JIA can also contain many neutrophils, levels are generally lower than with bacterial infection. Fluid should be sent quickly to the microbiology laboratory for Gram stain and culture. If this is not possible, then inoculating a blood culture bottle is acceptable, but this process may delay identification of pathogens. Though the culture is sometimes negative in cases that seem to be acute bacterial arthritis, the combination of clinical data and fluid characteristics help confirm the diagnosis. Positive joint fluid cultures are encountered in approximately 50% to 60% of cases caused by bacterial infection. A joint effusion with a low white blood cell count and normal glucose suggests that the arthritis may be caused by a sympathetic effusion from an adjacent osteomyelitis, or possibly an aseptic arthritis caused by a reactive arthritis or JIA or other rheumatologic diseases.

### Imaging

Early in the course of septic arthritis, bone changes are unlikely, but soft tissue changes may occur, including swelling and edematous infiltration into fatty tissue

planes. Plain films, however, should be obtained to evaluate for fracture or osteomyelitis if the infection has been present for more than 1 week. Ultrasonography has proved useful in detecting the capsular distention that accompanies septic arthritis of the hip. An experienced radiologist can define the presence of a joint effusion by ultrasound of the joint and, if a joint effusion is present, can assist the operator in accurate needle placement during diagnostic aspiration. Magnetic resonance imaging is sensitive and may be helpful in defining adjacent bony involvement and soft-tissue abscesses, especially in areas of complex anatomy such as the hip, sacroiliac joint, or pelvic bones. However, in clear cases of infection, therapy should not be delayed by waiting for this study to confirm a clinical diagnosis.

### MANAGEMENT

Joint aspiration with a large-bore needle is an important diagnostic maneuver, and an orthopedic surgeon or interventional radiologist skilled in the care of pediatric patients should be consulted to aspirate joints. Fluoroscopy or, possibly, ultrasonography, may be used to confirm entrance into the relatively inaccessible hip and shoulder joints. Failure to obtain pus from a joint that seems clinically to be infected can be caused by the thickness of pus in the joint, and open drainage of the joint may be necessary to confirm the diagnosis and to treat the infection.

Empiric therapy with antimicrobial agents that are appropriate for the likely pathogen should be started urgently after aspiration of the joint. Most infections are caused by *S aureus*; thus, an effective antistaphylococcal antimicrobial is almost always part of the initial treatment. A penicillinase-resistant penicillin, such as nafcillin or oxacillin, or a first-generation cephalosporin is often sufficient, though clindamycin or vancomycin should be considered given the incidence of methicillin-resistant *S aureus* (MRSA) in community-associated infection. In the child who is severely ill or has signs of bacteremia and sepsis, vancomycin should be considered as initial therapy instead of or in addition to a  $\beta$ -lactam.

A first-generation cephalosporin should not be used in a neonate as empiric therapy because of poor cerebrospinal fluid penetration and the concern for a bacteremia seeding the central nervous system. A safer approach would be to start empiric therapy with high doses of a penicillin that is effective for treating *S aureus*, such as oxacillin, combined with an antibiotic to treat gram-negative enterics, such as ceftazidime, cefepime, or an aminoglycoside. Once a pathogen is identified, therapy should be narrowed to treat the specific organism.

Broad coverage is also appropriate for the child who is immunocompromised and the adolescent thought to be abusing an intravenous drug as the cause of a bacteremia. Antibiotics selected empirically for such patients should be effective against *S aureus*, enteric Gram-negative bacilli, and *Pseudomonas*. A broad-spectrum penicillin such as ceftazidime or cefepime and an aminoglycoside with vancomycin might be empiric therapy in these children, pending final joint and blood cultures. The adolescent with possible gonococcal joint infection should be treated for staphylococci and gonococci until the diagnosis is clarified.

In this situation, cefuroxime or ceftriaxone, perhaps with vancomycin, might be selected, depending on the specifics of the case.

Parenteral antibiotic therapy is continued at least until the child is doing well and signs of acute infection have resolved. Oral therapy can be used to finish treatment. This approach is possible when an organism has been identified by blood or joint fluid culture and when an effective oral agent is available. Oral antibiotics can be used only if the child's social situation guarantees reliably that the antibiotics will be given as directed and the antibiotic does not cause a gastrointestinal disturbance that might interfere with absorption or adherence. The organism must be susceptible to the oral antibiotic, and the antibiotic must achieve therapeutic levels in bone and joint. Laboratory tests such as the sedimentation rate and C-reactive protein should be normalizing before switching to an oral agent. Antibiotic therapy should continue for a minimum of 3 to 4 weeks, but treatment should not be discontinued until the clinical response is complete and the markers of inflammation, such as the C-reactive protein level and erythrocyte sedimentation rate, have returned to normal. Treatment will be longer if concurrent osteomyelitis is present, and lengthening therapy is sometimes advisable if most of the course of therapy is oral.

A surgical referral is required because of the necessity to aspirate the joint and, at times, for diagnosis, surgery, and treating the infection. All children with septic arthritis of the hip should be seen emergently by an orthopedic surgeon, because these patients require immediate drainage of the joint. Delay in draining a major joint, such as the hip joint, is associated with poor outcome. Open debridement may be required. Other infected joints less often require open debridement but should also be evaluated for surgical treatment. Repeated aspirations of a joint may be necessary if fluid reaccumulates.

Septic arthritis is an emergent situation and requires consultation among the primary physician, orthopedic surgeon, and radiologist. Treatment is often coordinated by an infectious diseases specialist to aid in selecting an appropriate antibiotic, to monitor response, and to organize and coordinate follow-up after hospital discharge, which may include outpatient home intravenous therapy.

### WHEN TO REFER

Children who are being evaluated for bone or joint infection should be evaluated by an orthopedic surgeon or infectious diseases specialist.

### WHEN TO ADMIT

All children thought to have bacterial infection of a major joint should be hospitalized.

## Chapter 329

# SEXUAL ABUSE OF CHILDREN

John M. Leventhal, MD; Andrea Gottsegen Asnes, MD, MSW

Although sexual abuse of children has existed for centuries, only in the past 30 years have physicians come to recognize the scope of the problem, including its epidemiologic factors, clinical characteristics, approaches to management, and consequences to children and families.

## DEFINITION AND EPIDEMIOLOGIC FACTORS

Sexual abuse is defined as the involvement of children or adolescents in sexual activities that they do not fully understand, to which they cannot give informed consent, and that violate the social taboos of families or society. This type of abuse includes activities such as the sexual touching of a child's genitals by an adult or adolescent, sexual intercourse between an adult and child, the exposing of children to pornography, or involvement of children in prostitution. Sexual abuse should be distinguished from sexual play or exploration by preschool-aged or young school-aged children or sexual activities between consenting adolescents.

Child protection laws that were passed in the 1960s in each state initially required that cases of suspected physical abuse or neglect be reported, but shortly after were broadened to include children suspected of being sexually abused. Since 1976, national statistics of cases reported to each state's child protection agency have been compiled. The most dramatic increase in reports occurred in the 1980s as a result of increased publicity and increased recognition by

parents and physicians. In the 1990s, substantiated reports of sexual abuse peaked at more than 150,000 cases per year (representing approximately 13% of almost 1.2 million substantiated cases of child maltreatment). Since then, the number has decreased to a total of 61,000 substantiated reports of sexual abuse in 2013, the latest year for which complete data were compiled. These reports represent 9% of all substantiated reports of child maltreatment that year.

In 2013, of all reports made to protective services, approximately 20% were substantiated after investigation. The failure to substantiate an allegation does not necessarily mean that the abuse did not occur, but rather indicates that protective services did not have enough evidence to confirm the allegation.

Approximately 75% of children evaluated for suspected sexual abuse are girls. The age range is from 6 months to 18 years, with a median age of approximately 8 years.

Although such cases represent those reported to child protective services, an alternative approach to estimating the prevalence of the problem has been to interview adults about their childhood experiences of sexual abuse. These studies provide information about lifetime prevalence. A review of 19 studies conducted on community samples in the United States or Canada in the 1980s and early 1990s found that the rates of sexual abuse reported by women were 2% to 62% and by men were 3% to 16%. Finkelhor suggested that a summary statistic for women of 20% would be reasonable. Because only 9 of the studies in Finkelhor's review surveyed men, less certainty existed about a summary statistic for men, but a conservative estimate would be 5% to 10%. A 2009 study that aimed to update Finkelhor's previous work as well as add data from international studies found that these prevalence estimates remain consistent. The prevalence of sexual abuse reported by adults in different studies varies because of the population studied, the response rate, the number and types of questions asked, the definition of sexual abuse, the age used to define childhood, the accuracy of the adults' memories, and the adults' willingness to report past events.

Unlike cases of physical abuse or neglect, which are reported much more commonly in families who are poor and have limited education, cases of sexual abuse occur in families from all social classes and educational backgrounds. Perpetrators of sexual abuse are almost all boys and men, and nearly one-third of them are adolescents. Most children who are sexually abused know the perpetrator, who may be the father, stepfather, another male relative, a family friend, or an adult in the child's community. Since the 1980s, allegations of sexual abuse of children by clergy members in the Catholic church have been made in countries throughout the world, and these have done much to raise awareness about the problem of child sexual abuse. Although female perpetrators are unusual in most clinical series, these rates may be falsely low because of underrecognition. A small number of sexually abused children do not know the perpetrator; these victims are usually older children or adolescents who are victims of forceful sexual assault or rape.

## ETIOLOGY

Although physicians are able to understand how a parent might lose control and physically abuse a child, understanding how an adult can move from close bodily contact and even sensual feelings toward sexually abusing a child is much more difficult. Two prerequisites for sexual abuse to occur include the offender's sexual arousal to children and the willingness to act on this arousal. Studies have attempted to examine adults' sexual attraction to children. For example, 21% of male college students in an anonymous questionnaire indicated that they felt sexual attraction toward children. Some offenders may focus their attention on children of a certain age or gender; others may find themselves aroused only by children in certain circumstances. Factors that influence the offender's willingness to act on the aroused feelings toward the child include a lack of conscience about such behaviors, a lack of empathy for the child, a belief that such sexual behaviors are acceptable and not harmful to the child, poor impulse control, and the use of drugs or alcohol that might further decrease the ability to control behavior. Additional contributors to the likelihood that sexual abuse may occur include the history of the perpetrator (eg, having experienced sexual abuse during childhood), circumstances that allow the perpetrator to have increased contact with the child (eg, a mother hospitalized for a lengthy period), and the particular vulnerabilities of the child (eg, intellectual disability).

Children who are sexually abused are often selected because they seem particularly vulnerable or needy. Such children may initially enjoy and appreciate the attention that they receive from the offender, who may begin by giving the child gifts, attention, and special hugs and touches. These behaviors may progress to special secrets and eventually from nonsexual to sexual activities that lead to sexual intercourse. This process is labeled the child sexual abuse accommodation syndrome, which describes 5 stages that occur in the sexual abuse of children: (1) secrecy; (2) helplessness; (3) entrapment and accommodation; (4) delayed, unconvincing disclosures; and (5) later retraction of the alleged abuse.

## CLINICAL MANIFESTATIONS

Similar to other forms of family violence, sexual abuse of children often occurs in the privacy of a home or in a setting that involves only the abused and the abuser and is seldom witnessed by another person. A child who was sexually abused may have experienced other forms of maltreatment, including physical abuse or neglect, and certainly emotional abuse as well.

A physician's concerns about the possibility of sexual abuse occur because of reports of specific statements made by the child, usually to a parent or other adult, about uncomfortable experiences such as being touched on the genitalia, reports of specific behaviors of the child such as sexualized behaviors with a sibling, symptoms such as encopresis or vaginal discharge or bleeding, or a genital or anal injury noted on physical examination.

Clear statements by the child (or occasionally accidental direct observations of the sexual abuse) are the

best indicators that sexual abuse occurred. Young children are most likely to tell a parent or other close adult caregiver about abuse, but they may lack the necessary vocabulary to describe what happened to them. They may use words that the perpetrator used to encourage their participation (eg, "We played the hugging game") or words that describe their experience of what happened or how it felt but are confusing to the adults (eg, "He stuck a knife in my pee-pee"). Older children are as likely to tell a peer about abuse as they are to tell a parent and may begin by offering a guarded, vague disclosure (eg, "My uncle kisses too hard"). If an adult is told and reacts in a concerned manner with appropriate exploratory questions, then more details may follow. The older child may be embarrassed about what happened, feel partially responsible, experienced pleasurable feelings, or be concerned about the threats that the perpetrator made (eg, "If you tell your mother, I will punch you" or "If you tell, you know they will think you are a liar"). Even after a clear disclosure, once children realize how upsetting the information is to the family, they may retract the statement. Older children also may feel responsible for holding the family together: If the child tells, then the father will go to jail, the house will be sold, and everyone will be angry at the child; on the other hand, if nothing is said, then the sexual abuse will continue, but at least the family will be saved. Some children consciously or unconsciously sacrifice themselves for their family.

Children who were sexually abused may demonstrate a variety of symptoms and behaviors. Some may be relatively asymptomatic and able to function reasonably well in social settings and in school. Many children exhibit nonspecific symptoms such as sleep problems, generalized anxiety, suicidal gestures, or poor school performance, which are seen in response to other childhood stresses as well. A 2008 study of sexually abused girls found high rates of reported genital soreness and dysuria in those who disclosed genital-to-genital contact. Sexualized behaviors, such as excessive masturbation, the use of adult words associated with sexuality, or simulation of sexual intercourse with another child, animal, or doll, are more suggestive of sexual abuse. Other concerning symptoms include vaginal pain, bleeding, discharge, or rectal bleeding. However, even a symptom such as vaginal discharge has a low likelihood of being caused by sexual abuse. Several studies of premenarchal girls who complained of vaginal discharge show that the occurrence of sexual abuse is uncommon (<5%–10% of girls who have this complaint) and that the most common cause is poor hygiene.

Only a small percentage of sexually abused children will have an abnormal genital or anal finding. For example, a study of 2,384 children referred for possible sexual abuse to a tertiary referral center found that only 4% of them had an abnormal examination at the time of evaluation. Acute findings such as genital or anal abrasions may be more likely seen in the emergency department setting. However, the absence of physical findings does not rule out sexual abuse because no injury may have occurred to the genital area, or if an injury did occur, it may have healed without

leaving any physical signs. Even in cases in which the perpetrator is convicted of sexual abuse, having an abnormal examination is unusual for the victim. For example, in a series of 236 child abuse cases in which the perpetrators were convicted, only 23% of the victims' genital examinations were considered suspicious or abnormal in girls, and only 7% of anal examinations were considered so in boys and girls. Even in pregnant adolescents who are examined for suspected sexual abuse, physical findings indicating sexual abuse are unusual. In a case review of 36 pregnant adolescents evaluated for sexual abuse, only 2 of the 36 girls had definitive findings of penetration. The authors of this study suggest 2 possible explanations for this finding: Penetration does not result in visible tissue damage, or acute injuries occur with penetration but heal completely. These studies highlight both the limited role of physical findings in the investigations of sexual abuse and the crucial role of the child's history of the abuse.

During the past several years, research has defined normal and abnormal genital and anal anatomic features in prepubertal children and adolescents. Several studies have described the variations in the anatomic features of the hymen in female newborns and have concluded that the hymen is present in all normally developed newborns. The appearance of the hymen is often thickened early in life because of the effects of maternal estrogen in utero; in preschool-aged and school-aged girls, the hymenal tissue becomes thinner until the effects of estrogen during puberty result in a thickening of the tissue and the development of redundant folds. Studies of normal prepubertal girls have described the shapes of the hymen as crescentic, annular, and fimbriated (or redundant) and have noted the frequency of normal variations, including hymenal mounds, intravaginal ridges, and adhesions of the labia minora. These studies have provided data on the means and ranges of the vertical and horizontal diameters of the hymenal orifice in different age groups, the variations in diameter depending on how the genital examination is performed (eg, separation versus traction of the labia majora), and the width of the posterior hymenal rim.

Children who are sexually abused may have acute injuries of the genitalia, including acute lacerations, abrasions, or hematomas. However, most children who are sexually abused do not disclose until weeks or months after the occurrence of the abuse. In such children, findings that are considered suspicious or suggestive of past abuse include U- or V-shaped clefts (or notches) of the posterior rim (from 3 o'clock to 9 o'clock) of the hymen, which occur in the healing process after an acute laceration, and attenuation or decreased width of the hymenal tissue posteriorly (<1 mm). These findings should persist when the child is examined in the prone, knee-chest position. A study of 192 prepubertal girls between the ages of 3 and 8 years who had a history of penetrating sexual abuse and 200 who denied prior abuse detected few differences in anatomic findings between the abused and nonabused samples. A few specific hymenal findings were evident, however, that were noted in 4 girls in the abused group and not in the comparison group.

These were hymenal deep notches, perforations, or transections, and each was noted in a girl who disclosed penetration. Scarring, such as of the posterior fourchette, is also indicative of previous trauma. Although, in the past, investigators considered an enlarged horizontal diameter of the hymen of greater than 4 mm to be suspicious of previous sexual abuse in prepubertal children, studies of normal children indicate that this demarcation is incorrect and that the size of the opening varies with the child's age and different examination techniques, as well as with the child's state of relaxation. A horizontal diameter of greater than 10 mm may concern a physician about the possibility of sexual abuse but should not be used by itself to make a diagnosis.

Data about normal physical findings in adolescence are limited; 1 study compared 3 groups of female adolescents: (1) those who denied sexual intercourse and used only pads for menses, (2) those who denied sexual intercourse and used tampons, and (3) those who experienced sexual intercourse. Although significant differences were found in the median horizontal diameters of the hymenal orifice in the 3 groups (1.2, 1.5, and 2.5 cm, respectively), overlap certainly existed among the groups. In addition, a striking difference among the groups was that of the sexually active teenagers: 81% had a complete cleft (or V-shaped notch) between the 2-o'clock and 10-o'clock positions on the hymenal border compared with 11% in tampon users and 5% in pad users.

A 2004 study of 85 girls between the ages of 13 and 19 years improved on these data by using a colposcope for magnification and photographic documentation of hymenal morphologic features. In this study, posterior hymenal notches and clefts were more common in girls admitting past intercourse (48%) than in girls who denied intercourse (3%). The 3% of girls who denied intercourse and had posterior hymenal clefts described a painful first experience with tampon insertion. Of note, the mean width of the posterior hymenal tissue was not significantly different between girls who admitted and those who denied past intercourse.

Abnormalities of the male genitalia caused by sexual abuse are unusual. However, acute abrasions, lacerations, or bruises caused by physical abuse can be seen.

Acute anal findings, such as lacerations resulting from anal penetration or injury, have been noted in sexually abused children, but few systematic studies of perianal findings in chronically abused children have been conducted. Worrisome findings include thickening of the rugae, distorted anatomy secondary to scarring, and dilation greater than 2.0 cm (when the child is in the prone, knee-chest position and no stool is visible in the rectal ampulla). In a study of children with documented anal injuries followed from acute injury to healing, 29 of the 31 children healed completely, with scar formation only in the 2 cases requiring acute surgical repair. A study of normal prepubertal children highlighted common normal findings that were noted when the child was examined in the prone, knee-chest position; these included skin tags in the midline, fan-shaped areas in the midline superiorly,

perianal erythema, venous congestion, and anal dilation up to 2.0 cm.

Children who are sexually abused may acquire a sexually transmitted infection (STI). Controversy continues about how children acquire such diseases, in part, because of the social and legal implications and because of the difficulty in believing that a young child's infection is from sexual contact. Approximately 5% of sexually abused children acquire an STI from the perpetrator of the abuse. According to a 2005 clinical report published by the American Academy of Pediatrics, the presence of *Neisseria gonorrhoeae*, syphilis, or *Chlamydia trachomatis* is diagnostic of sexual abuse in prepubertal children in whom perinatal transmission and rare, nonsexual vertical transmission are excluded. The presence of human immunodeficiency virus (HIV) infection in prepubertal children is diagnostic of sexual abuse in those in whom perinatal and transfusion-related acquisition are excluded.

Human papillomavirus (HPV) presents a special case in the evaluation for possible sexual abuse. Condylomata noted in 12- to 24-month-old infants were previously thought to be the result of perinatal transmission. Recent work determined that vertical transmission is either not a common source of HPV infection or not a source of infection at all. Recent epidemiologic data suggest that many preadolescent children acquire HPV from nonsexual horizontal transmission, either by autoinoculation if a child has common skin warts or horizontally from nonabusive contact by a person who has common warts, and that the likelihood of sexual abuse as a possible cause increases with age. History and full medical evaluation are of particular importance in ascertaining the possibility of sexual abuse in a child with HPV.

Pubertal female victims are at risk of pregnancy from sexual abuse. Adolescents who become pregnant from sexual abuse often try to hide the pregnancy and can be extremely reluctant to name the perpetrator. If the perpetrator is a family member, then the psychological consequences for the adolescent and nonoffending family members can be particularly complex and debilitating.

## ASSESSMENT AND DIAGNOSIS

The pediatrician may learn about suspected sexual abuse from concerns raised by parents, direct statements from the child, or abnormalities noted on physical examination or laboratory tests. When sexual abuse is suspected, an important decision point is whether the concerns or suspicions meet the requirement of mandatory reporting to the local child protective service agency. In most states, the requirement to report is based on the level of reasonable suspicion.

When initially evaluating possible sexual abuse, the pediatrician should take 5 important clinical steps. First, a careful decision about how much history to obtain directly from the child should be made. Many locales can provide timely, subspecialty-level evaluation for suspected sexual abuse. When such care is available, only a minimal history or, in some circumstances, no direct history will be necessary because

the child will be interviewed by a specially trained forensic interviewer (with representatives of the police and child protective services observing).

Second, the primary care physician should decide the extent of the physical examination to be performed and whether the collection of laboratory or forensic data is indicated. A brief external examination to rule out acute trauma can be performed with referral for emergency care only in the event that acute trauma is present. If the child has symptoms of an STI, then appropriate laboratory tests should be obtained. If the pediatrician evaluates the child within 72 hours of the last occurrence of sexual abuse, then forensic evidence may need to be collected in an emergency department setting. Parents should be advised to preserve in a paper bag any unwashed clothing or bedding with which a suspected perpetrator may have been in contact for possible forensic evaluation.

Third, careful documentation in the medical record of collected information must be performed.

Fourth, the physician should meet with nonoffending parents (and the child, if old enough) to explain that a report will be made to child protective services and that an investigation will be conducted in the community.

Fifth, and finally, follow-up with the family should be arranged so that the pediatrician can offer ongoing support during the ensuing forensic evaluation.

Many communities have children's advocacy centers (CACs), multidisciplinary teams (MDTs), or both, that provide a rational and coordinated approach to the evaluation of children who may have been sexually abused. Children's advocacy centers provide comprehensive, multidisciplinary assessments of abused children in an environment designed to be both neutral and child friendly. In addition to medical evaluations, Children's advocacy centers may house needed mental health services for children and their families. Multidisciplinary teams members can include representatives from the local police, prosecutors' office, and protective services, and experts in interviewing and examining the child. Multidisciplinary teams meetings provide an opportunity to discuss specific cases resulting in coordinated investigative and treatment efforts for each abused child and a forum for community-wide efforts in prevention and early detection of child sexual abuse. Shared goals of CACs and MDTs are minimizing secondary trauma experienced by the child and family resulting from the investigation and improving case investigations leading to more successful prosecutions.

As part of the evaluation, the subspecialty physicians should consider alternative explanations, including an unintentional injury (or *accident*), a medical problem, or a false allegation. Because evaluations for suspected sexual abuse usually include the child protection and legal systems, care should be taken to provide an unbiased assessment and one that provides documentation that can be reviewed by professionals outside the medical system.

### History

The purpose of the history is to understand what may have happened to the child. This history should

include the events that led to the evaluation, the child's health status and level of development, and the family's strengths and weaknesses. The parents (or guardians) should be asked what the child has said, how the child reacted when telling about the abuse, and whom the child told. Information should be obtained about (1) the child's behaviors, such as changes in behaviors or attitudes toward a specific person or situation, recurrent fears or nightmares, or sexualized behaviors; (2) specific symptoms, such as vaginal bleeding or discharge, dysuria, anal bleeding, constipation, and encopresis; and (3) where the child spends time and who cares for the child. Also to be determined are who the alleged perpetrator is, the relationship with the child, and the amount of time spent with the child. In preparation for interviewing the child, knowing about the child's developmental history is important, for example, whether a language delay is present.

The family history should include information about the parents' physical and mental health, including a history of sexual abuse during childhood; the health and developmental status of the siblings; the presence of family violence, substance abuse, or recent stresses; and the resources and supports available to the family. Understanding how family members view the allegations and how they have reacted is important. Because allegations that arise during a custody fight between parents are often difficult to sort out, the physician should determine whether the parents are separated or divorced, the custody arrangements, the visitation schedule, and any dispute about custody or visitation. Distinguishing whether the allegations of abuse occurred before the separation or divorce, during the process of separation and divorce, or after the divorce was finalized is helpful.

A child who is old enough to be interviewed directly should be asked about what may have happened. Pediatricians should perform minimal interviewing to obtain enough information to warrant a report to child protective authorities. Trained, forensic interviewers can then obtain a full disclosure that can be used as evidence in any legal proceedings stemming from the allegations. The development of forensic interview protocols, such as the National Institute of Child Health and Human Development Protocol for Investigative Interviews of Alleged Sex-Abuse Victims, allow for standardization of techniques, more elicited detail, and minimalization of trauma to the interviewed child. This interview or series of interviews should be conducted with the child alone, if possible. The interviewer should be comfortable and skilled at interviewing young children about the possibility of sexual abuse, use simple questions, and be aware of the child's nonverbal responses and direct statements. Leading questions, such as, "Didn't he touch your pee-pee?" should be avoided, when possible. Nonleading questions are preferable, such as, "Can you tell me what happened?" or "Where did he touch you?" In many instances, however, children are reluctant to talk because of a variety of reasons, including fear and embarrassment; in such cases, questions with forced choice responses, such as, "Was it your mother or father or teacher who did that?" or "Was his pee green or pink or white?" can be helpful.

To help young children during the interview, anatomic drawings or anatomically correct dolls have been used. Considerable controversy has occurred about the sexual nature of the dolls and whether their use suggests to children that they can talk about sex, thus leading to false allegations. However, research indicates that few nonsexually abused children respond in sexual ways with the dolls and that the dolls can be helpful to children in describing what happened. Because of the controversy involving the dolls, most interviewers prefer not to use them. Some older children who have difficulty verbalizing acts of sexual abuse may be able to draw pictures of or write out a description of what occurred.

### Physical Examination

The purposes of the physical examination are to determine the presence or lack of (1) signs of physical abuse or neglect, (2) anogenital injuries that are consistent with or suggestive of sexual abuse, and (3) conditions that need medical treatment. In addition, the examination provides an opportunity for the physician to reassure the child and family about the child's physical condition. In premenarcheal girls, the genital examination is performed best in both the supine and the prone, knee-chest positions; a speculum is seldom used. To visualize the hymen, 2 physical examination maneuvers should be used: (1) labial separation (separating and pulling posteriorly at an angle of 45 degrees) and (2) labial traction (gently pinching the labia and pulling out and toward the examiner). Evaluations conducted in specialty centers rely on the use of a colposcope during the anogenital examination to provide 5- to 30-fold magnification and documentation through photographs or videotape recordings. A study comparing examinations with and without the use of the colposcope indicated that more than 95% of physical findings can be detected without its use. A handheld magnifying lens that provides 2.5- to 3-fold magnification or an otoscope (without a speculum) can provide reasonably good magnification.

### Laboratory Tests

When the child is at risk of acquiring an STI from suspected sexual contact, appropriate tests should be obtained for gonorrhea, herpes simplex, trichomonas, bacterial vaginosis, chlamydia, syphilis, HIV, and hepatitis B and C infections. Historically, cultures for *N gonorrhoeae* and *C trachomatis* were considered the gold standard for diagnosing infection with these organisms. Many medical settings have forgone culture in favor of newer tests, such as nucleic acid amplification tests that detect the presence of the organism's DNA or RNA. A particular advantage of these tests is that they may be run on urine samples as opposed to vaginal or urethral swabs. Data regarding the use of these tests in prepubertal children are scarce, and the prevalence of these infections in children is very low. As nucleic acid amplification tests are increasingly used, their importance both clinically and legally can be expected to increase. Currently, the Centers for Disease Control and Prevention suggest the use of nucleic acid amplification tests for the detection of *N gonorrhoeae* and *C trachomatis* because of the tests'

increased sensitivity over culture. That many medical centers no longer offer culture for *C trachomatis* suggests that newer tests will take on increasing significance in the future. For a child who has a vaginal discharge, additional studies may be performed to test for trichomonal or bacterial vaginosis. Serologic samples may be analyzed for HIV, hepatitis B and C, and syphilis. Although universal screening is recommended for postpubertal children, the decision to screen for these infections in prepubertal children should be guided by the nature of the sexual contact and the signs and symptoms in the child, the presence of another STI, the risk status of the perpetrator, family wishes, and the discretion of the medical provider.

Studies have attempted to determine which children should be tested for STIs. For example, in a review of 2,731 preteens who had vaginal cultures, 84 (3.1%) had gonorrhoeae, and 80 of these had a vaginal discharge. However, no data are available to help determine which children should have cultures taken from all 3 sites: the genitals, throat, and anus. If the child has evidence of 1 STI, conducting a full range of tests for other STIs would then be reasonable.

The collection of forensic evidence is an important component of evaluating victims of sexual assault. When an adolescent is evaluated within 72 hours of an episode of suspected sexual abuse, appropriate forensic information, such as swabs to detect semen, should be collected (see Chapter 371, Rape). However, the DNA and epidemiologic factors of forensic evidence findings in prepubertal victims of sexual abuse suggest that the collection of this evidence has a low yield. A study of forensic evidence findings in 273 prepubertal children in whom abuse was suspected revealed that the likelihood of useful evidence collection 24 hours after an acute assault is extremely low. Swabbing a child's body for evidence is therefore indicated within the 24-hour period immediately after an acute sexual assault. The same study showed that clothing and linens from sexually abused children provided a significantly higher yield of forensic evidence after an acute sexual assault than samples taken directly from the child. These items should be rigorously pursued for analysis in the setting of an acute sexual assault. In pubertal girls, a pregnancy test may be necessary.

### Documentation

Documentation of the evaluation should include direct quotations, when appropriate, from the parents and the child and a clear description of the findings from the physical examination, with sketches, if necessary. In many states, the information is recorded on a specific form for suspected sexual assault. A videotape of the child's interview and videotape or photographs of the examination provide additional detailed information; these should be labeled with the date, child's name, physician's name, and child's medical record number.

### DIFFERENTIAL DIAGNOSIS

Conditions that need to be considered in the differential diagnosis depend on the child's symptoms and physical findings. Some of the physical findings that

can be seen in sexually abused children also are non-specific findings, such as erythema of the vulva or introitus. Bruises to the genital or anal area should raise concern about physical abuse, but if bruising is more widespread, then medical conditions, such as bleeding disorders, need to be considered. Straddle injuries, which can affect the genitalia, are usually witnessed, and thus the history is clear. These types of injuries are usually unilateral or anterior and produce obvious bruising and swelling of the external genitalia; affecting the hymen is unusual for such injuries because of the protection provided by the labia and bones of the pelvis.

An important dermatologic condition that may exhibit genital soreness and subependymal hemorrhages is lichen sclerosus. This condition usually affects the vulva and perianal region and produces an hourglass appearance, with areas of subependymal hemorrhage, decreased pigmentation, and tissue friability. Urethral prolapse can produce vaginal bleeding and dysuria, and the abnormalities noted on physical examination might be considered the result of trauma from sexual abuse. Another condition that may be mistaken for sexual abuse is a streptococcal infection, which can cause marked redness of the perianal region and a vaginal discharge. For children who have a foul-smelling vaginal discharge, a foreign body should be considered in the differential diagnosis.

A critical challenge for the examiner is to identify abnormalities that are caused by trauma from sexual abuse versus normal variations. Studies have shown that physicians do not always agree on their descriptions or interpretations of genital findings. For example, Paradise and colleagues used 7 simulated cases to compare the assessments of 206 US physicians who considered themselves skilled at examining sexually abused children with the assessments of a panel of experts. Not surprisingly, the most experienced physicians were more likely than the less experienced physicians to agree with the ratings of the expert panel. In a related study, the history provided in a simulated case was noted to have an influence on physicians' interpretations of findings: when the history did not suggest sexual abuse, the physicians (especially those who had little experience) were more likely to consider the examination normal. The opposite effect was found as well: when the history suggested sexual abuse, physicians were more likely to consider the same examination as abnormal.

The possibility of a false allegation also should be considered in the differential diagnosis. Although false allegations seem to be uncommon, controversy exists about the accuracy of young children's memory, under what circumstances they can be asked leading questions that result in false reports of what happened, and how relevant these studies are to children's reports of sexual abuse. False allegations should be carefully considered if the child has a serious mental health problem or if the child's statements lack detail about the event, have important inconsistencies, or seem rote in nature. If the child is part of a bitter dispute between the parents (eg, a custody fight), a false allegation, although rare, must also be carefully considered.

## MANAGEMENT AND TREATMENT

Management of children who are suspected of having been sexually abused includes action in 3 domains: (1) providing appropriate medical care, (2) reporting the case to protective services, and (3) ensuring mental health services for the child and family.

Guidelines for the treatment of STIs are highlighted in Chapter 371, Rape. In addition, counseling may be necessary about the implications of certain infections, such as HPV or HIV. Occasionally, surgical repairs of genital or anal injuries are necessary, and adolescents may need counseling about terminating a pregnancy that resulted from sexual abuse. A major purpose of the physical examination is to provide reassurance to children and families that their bodies are physically intact. When abnormalities are noted on the physical examination, reassurance often can be provided by indicating that these likely will heal and be of little functional importance to children.

Physicians who suspect sexual abuse are mandated to report their findings to the state's child protection agency. Because sexual assault is a criminal offense, the local police also participate in the investigations. Issues that need to be considered include the following: to what extent the children should be interviewed further, by whom, and in what setting; where the children should go to ensure their safety; and whether other children in the home need an evaluation.

The period after the child's disclosure can be emotionally upsetting to everyone involved and especially confusing to the child. Repeated interviews of the child (by well-meaning professionals, such as police or a protective service worker) may upset the child, who may be confused about why so many people are asking questions, embarrassed about talking about private parts, and worried about the family's reactions. Family members may blame themselves for allowing the abuse to happen and be furious at the suspected perpetrator. If the abuser is a relative, then the family may be divided, with the child's side believing the child and the abuser's side believing that the abuse could not happen and that the child is lying. If the abuser is in the immediate family, then the psychological issues are even more complicated. For example, a mother may have to decide between siding with and supporting her child or believing that her child lied and supporting her husband. If her husband did sexually abuse their child, then the mother may question her ability to protect her child, her own sexuality, and her ability to choose a partner; at the same time, she may be concerned about how the family will be supported with the father in jail.

The physician can be helpful by maintaining contact with the family, advocating for a reasonable approach by protective services (eg, having the alleged abuser leave the home rather than place the child in foster care), and helping the family to recognize and discuss the various emotional issues that surface.

When a child discloses sexual abuse, a chain of events is set in motion that has immediate and often distressing consequences for the child. What was once a secret for the disclosing child becomes a very public and emotionally charged event. Not only do

children feel guilty for causing this upheaval, but they must also endure potentially terrifying interactions with child protective services and law enforcement. Parents are often overwhelmed by their own reactions to a child's disclosure; intense anger, fear, blame, and helplessness can be very strong and can cause acute distress and significant disturbances in functioning.

Most sexually abused children and their parents need short- or long-term counseling to help come to terms with what happened. Recent work has shown that a cognitive behavioral treatment model that focuses specifically on the sexual abuse of the child and involves both the child and nonoffending parents has achieved measurable improvement in children's functioning in the wake of sexual abuse. Furthermore, the presence or absence of parental support is directly correlated with children's functioning, even as long as a year after disclosure. This finding highlights the importance of involving nonoffending parents, especially those in obvious distress, in counseling.

Because sexual abuse of a child is a criminal offense, the child and family are often involved in the criminal justice system. However, despite this involvement most cases do not actually result in a trial in criminal court for a variety of reasons, including lack of clear evidence that abuse occurred, the young age of the victim, a confession of the perpetrator, or the willingness of the perpetrator to plea bargain for a lighter sentence. In approximately 3% to 5% of cases, a criminal trial is held in which the child actually testifies. Additionally, sexual abuse cases sometimes are tried in family court when allegations of sexual abuse occur as a part of a divorce or custody proceeding or in juvenile court when protective services are concerned about the child's safety in the home.

## PSYCHOSOCIAL CONSEQUENCES

Sexual abuse can have a long-lasting and devastating effect on the development of children, adolescents, and adults. Domains of functioning that can be affected include the survivor's emotional state (eg, depression, anxiety, suicide), sense of self (eg, feeling worthless or powerless, viewing one's self as a victim), and relationships with others (eg, setting poor boundaries, being promiscuous, using inappropriate sexual behaviors, mistrusting others). Important targets for long-term treatment include self-blame for allowing the abuse to happen, the child's sexuality and sexual awareness, poor self-esteem and feelings of powerlessness, and mistrust of adults. For example, school-aged and adolescent boys may be very concerned about their own masculinity and whether, because they were abused by an older boy or a man, they are gay. At the same time, because of changes in the family (eg, the child no longer visits the grandfather), the child has to come to terms with the losses created by the disclosure and the upset and anger in the family.

Teenage girls and young women seem to be at an increased risk for other mental health problems, such as eating disorders, multiple personality disorders, and posttraumatic stress disorders. They are also more likely to become pregnant at a young age.

Men who were sexually abused as children are at increased risk for having mental health or substance abuse problems. They are also more apt to perpetrate sexually coercive acts, including victimizing children sexually.

## PREVENTION

Attempts to prevent sexual abuse have been directed toward developing programs to teach children, usually at school, about *good and bad touches* and what to do if bad touches occur. Children as young as 4 to 6 years are able to learn these concepts and retain them, at least over a short period. In general, evaluations have focused on the children's increased knowledge resulting from participation in a teaching program but have not been able to provide conclusive evidence that such programs actually have resulted in the prevention or earlier recognition of sexual abuse.

## Chapter 330

# SEXUALLY TRANSMITTED INFECTIONS

Alain Joffe, MD, MPH

Fifteen- to 24-year-olds represent only a quarter of sexually active individuals in the United States, but almost one-half of all sexually transmitted infections (STIs) occur in this age group. Several possible explanations can be given for this observation (see Box 330-1). Rates of sexual activity among adolescents have decreased steadily since 1991, but according to the 2013 Youth Risk Behavior Survey conducted by the Centers for Disease Control and Prevention (CDC), 47% of teenagers have had sexual intercourse and therefore are at risk of acquiring an STI. By virtue of their cognitive developmental level, adolescents often feel invulnerable and underestimate their potential for becoming infected. They may ignore symptoms or think that as long as they (or their sex partners) are free of symptoms, they are neither at risk of being infected nor capable of infecting someone else.

A physiologic basis may be found for adolescent girls being particularly susceptible to infection with a sexually transmitted organism on exposure. The transformation zone of the pubertal cervix, which has a relatively large surface area compared with that of a mature woman, is particularly vulnerable to infection with *Chlamydia trachomatis* and human papillomavirus. Not surprisingly, therefore, current data indicate that adolescent girls and young adult women have higher infection rates with these organisms than any other age group in the United States. Recent age-specific infection rates from the CDC for *C trachomatis* and *Neisseria gonorrhoeae* are shown in Figure 330-1. Rates of infection among 10- to 19-year-olds may actually be higher than indicated because the pool of truly susceptible individuals (those sexually active) is smaller in this age group than in the older groups. For example, only 46% of 9th to 12th graders have had intercourse compared with most adults.

Many studies indicate that consistent and correct use of condoms provides significant protection against STIs, although the degree of protection varies by organism. Adolescents' reported use of condoms at last intercourse increased by more than 30% since 1991, but still 41% did not use a condom the last time they had sex. Furthermore, many teenagers do not use condoms consistently or correctly. In contrast to the protective

### BOX 330-1 Why Adolescents Are at Risk for Sexually Transmitted Infections

- Sense of invulnerability ("It can't happen to me")
- Lack of information ("If I don't feel sick, I can't be sick")
- Inconsistent and improper use of condoms
- Poor communication skills with partners and physicians
- Barriers to care (legal obstacles, concerns about confidentiality)
- Inability to adhere to treatment regimens
- Contextual risk factors (sexual networks with high prevalence of infection, partner concurrency, mating patterns)
- Physiologic changes associated with puberty

effect of condom use, the relationship between hormonal contraceptive use (such as oral contraceptive pills or depot medroxyprogesterone acetate [DMPA] injections) and risk for STI acquisition is more complex. Use of oral contraceptive pills may increase the risk for chlamydial infection but also decreases the risk for infection with *N gonorrhoeae* and development of symptomatic pelvic inflammatory disease (PID). Women receiving DMPA injections have been shown to be at increased risk for chlamydial infection but decreased risk for gonococcal infection. No data have been collected for other forms of hormonal contraception.

Adolescents often have trouble discussing sexual matters with their partners or their parents and may be reluctant to reveal that they are infected or have been treated. They may postpone a visit to a physician because they are embarrassed, fear a lecture, are concerned about the physician maintaining confidentiality, or lack the money or social skills to access health care. Some physicians hesitate to provide confidential services to an adolescent with a suspected STI because they are uncertain about the adolescent's capacity to consent to treatment without parental involvement. Currently, all 50 states have laws that permit a physician to treat most minors seeking treatment for STIs without parental consent or notification.

Analysis of individual-level risk factors (age, gender, condom use, pubertal status) explains only to a degree the striking differences in STI rates among various racial and ethnic groups. More recent research focuses on contextual risk factors: mating patterns (with whom one has sex and the sexual risk profile of that partner), sexual networks (sex partners drawn from networks with high or low rates of STIs), and partner concurrency (an individual may be unaware that his or her sex partner is having sex with more than 1 individual). Each of these dynamics helps to explain why different racial, ethnic, and socioeconomic groups, each with seemingly similar sexual behaviors, have significantly different rates of infection.

The list of organisms that can be transmitted sexually is extensive. Box 330-2 lists the most common. Gonorrhea, chlamydia, herpes, human papillomavirus,

**Figure 330-1** Rates of infection (per 100,000) with *C trachomatis* (CT) and *N gonorrhoeae* (GC), by age and sex, United States, 2009. (Data from Centers for Disease Control and Prevention. Sexually Transmitted Disease Surveillance 2009. Atlanta, GA: US Department of Health and Human Services; 2010.)

### BOX 330-2 Sexually Transmitted Organisms

- *Campylobacter species*
- *C trachomatis*
- Cytomegalovirus
- *Entamoeba histolytica*
- *Giardia lamblia*
- Hepatitis A, B, and C
- Herpes simplex virus types 1 and 2
- Human immunodeficiency virus
- Human papillomavirus
- Molluscum contagiosum (papovavirus)
- *Mycoplasma genitalium*
- *Mycoplasma hominis*
- *N gonorrhoeae*
- *Phthirus pubis* (pubic lice)
- *Salmonella species*
- *Sarcoptes scabiei* (mites)
- *Shigella species*
- *Treponema pallidum*
- *Trichomonas vaginalis*
- *Ureaplasma urealyticum*

and syphilis are discussed in detail in this chapter. Herpes infections are also discussed in Chapter 267, Human Herpesvirus-6 and Human Herpesvirus-7 Infections; Chapter 268, Human Immunodeficiency Virus Infection and Acquired Immunodeficiency Syndrome, reviews HIV infection and AIDS. Chapter 205, Vaginal Discharge, provides an overview of organisms

causing vaginal discharge. Information about other STIs should be sought through the index.

An alternative way of conceptualizing the spectrum of health problems attributable to STIs is to focus on symptoms or diseases rather than on specific organisms. More than 1 organism can produce various symptoms, physical findings, or syndromes, and some teenagers may be reluctant to disclose their sexual activity or deny it altogether. A recent study found that approximately 10% of young adults who tested positive for an STI denied having had intercourse in the 12 months prior to the survey. Hence, when an adolescent seeks care for symptoms and clinical findings that might be caused by an STI, the physician must proceed with appropriate diagnostic tests or therapy, even though the history may seem to exclude such a cause. Most sexually active teenagers, however, will be truthful when questioned respectfully without a parent or guardian present and when given appropriate guarantees about confidentiality. Box 330-3 lists a variety of symptoms and syndromes that are often caused by STIs.

Primary care physicians generally concern themselves with the short-term morbidity associated with STIs, but the complications of infection extend into adulthood. Cervical cancer, infertility, ectopic pregnancy, chronic pelvic pain, and AIDS are all long-term sequelae of infections acquired during adolescence and young adulthood. In addition, research has demonstrated that those individuals infected with 1 or more STIs are more likely than those without infection both to acquire HIV infection and to transmit HIV to an uninfected partner. STIs may cause a breakdown of the genital mucosa (providing a portal of entry for HIV) and recruit CD4 cells to the area of infection. However, STI acquisition may be a marker for other

### BOX 330-3 Signs, Symptoms, and Clinical Syndromes Consistent With Sexually Transmitted Infections in Adolescents

#### BOYS

- Dysuria, discharge, urethral itching (urethritis)
- Scrotal pain, swelling (epididymitis)
- Rectal discharge, tenesmus, anorectal pain (proctitis, proctocolitis, colitis)<sup>a</sup>

#### GIRLS

- Mucopurulent cervicitis
- Vaginitis (vaginal discharge)
- Dysuria, urgency, frequency
- Right upper quadrant abdominal pain (perihepatitis)
- Pelvic inflammatory disease (lower abdominal/pelvic pain)
- Bleeding between periods (cervicitis) or a heavier, more prolonged period (pelvic inflammatory disease)

#### BOTH

- Dermatitis<sup>b</sup>
- Genital ulcers (single or multiple)
- Genital warts
- Hepatitis A, B, or C infection
- Lymphadenopathy, especially inguinal or generalized (associated with human immunodeficiency virus infection)
- Persistent pharyngitis
- Septic arthritis

<sup>a</sup>Usually seen in adolescents who practice anal receptive intercourse or oral–anal contact.

<sup>b</sup>Especially generalized papulosquamous (secondary syphilis); papular with central umbilication (molluscum contagiosum); localized pubic itching, or localized itching involving the webs of fingers and the wrists (*Phthirus pubis*, pubic lice; or *Sarcoptes scabiei*, mites); and erythematous macules turning pustular or necrotic, accompanied by tenosynovitis (disseminated gonococcal infection).

unmeasured behavioral characteristics that contribute to the observed link between STI and HIV acquisition and transmission. Hence, while research published in the 1990s suggested that control of STIs could reduce the incidence of HIV infection, more current evidence indicates the effect of STI treatment on HIV incidence rates will also vary as a function of the sexual behaviors and STI prevalence of the population being targeted.

Regardless, the short- and long-term sequelae of STIs underscore the importance of preventing, diagnosing, and treating STIs among adolescents. The increasingly widespread availability and use of nucleic acid amplification tests (NAATs) for the diagnosis of *C trachomatis* and *N gonorrhoeae* infections represent major advances in achieving this goal. These tests are more sensitive than both culture and previous generations of nonculture tests, do not require the recovery of viable organisms, and can be performed on urine specimens or self-obtained vaginal swabs. By eliminating or reducing the need for invasive testing,

NAATs have the potential to expand greatly the number of at-risk youth who are screened. A urine NAAT is the preferred test for detecting chlamydia among males; self-obtained vaginal swabs are the preferred method for chlamydia detection among asymptomatic females, with a sensitivity that exceeds that of urine specimens and that is equal to or better than cervical swabs.

## SPECIFIC AGENTS

### *Chlamydia trachomatis*

The obligate intracellular *Chlamydia* microorganism causes a wide spectrum of disease and is the most common sexually transmitted bacterial organism in the United States. Of greatest importance is its causative role in urethritis and epididymitis in men and cervicitis and PID in women.

*Chlamydia* is thought to cause 35% to 50% of symptomatic nongonococcal urethritis (NGU) among heterosexual men. The organism can also be recovered from men with urethral gonorrhea. Approximately 2% to 10% of asymptomatic adolescent boys will test positive for chlamydia, depending on the population studied. In a recent national study of young adult men ages 18 to 26, a total of 3.7% tested positive for chlamydia (with a range of 1% to 11%, depending on the racial or ethnic group studied). Ninety-five percent reported no symptoms in the 24 hours before urine collection. When symptoms do appear, they generally develop 1 to 3 weeks after infection. Male adolescents may complain only of mild dysuria or itching at the terminal urethra, or they may have a scanty, mucoid discharge that is easily ignored and may disappear without treatment. The best time to examine an adolescent with a suggestive history but no discharge is in the morning, before he has urinated that day. Alternatively, having him strip his urethra may produce some discharge. A profuse, purulent discharge should raise the possibilities of *N gonorrhoeae* coinfection or of its being the single causative agent. Adolescents also may complain of testicular pain, scrotal pain, or both, suggesting that urethral infection has spread to the epididymis.

Because the organism can infect the urethra and the cervix, dysuria can be the primary manifestation of infection. *C trachomatis* infection should therefore be considered in any adolescent girl with symptoms of a urinary tract infection. She may complain of spotting between periods as a result of cervicitis, or if the infection has spread to the upper genital tract, she may complain of low abdominal pain or right upper quadrant pain (Fitz-Hugh–Curtis syndrome). The latter is caused by organisms tracking up the abdominal cavity and causing inflammation of the liver capsule along with adhesions to the diaphragm. Unless a thorough history is obtained, the combination of dysuria and right upper quadrant or right flank pain might lead a physician to the erroneous diagnosis of pyelonephritis. Lower abdominal pain suggests the possibility of PID. Vaginal discharge is more likely to indicate the presence of another infection (see Chapter 205, Vaginal Discharge), although chlamydia may be found incidentally. *C trachomatis* also may infect the Bartholin

**Figure 330-2** Colposcopic photograph showing mucopurulent cervicitis before and 2 weeks after treatment with 500 mg of tetracycline 4 times a day for 7 days. Note disappearance of endocervical exudate after therapy. (From Brunham RC, Paavonen J, Stevens CE, et al. Mucopurulent cervicitis—the ignored counterpart in women of urethritis in men. *N Engl J Med.* 1984;311:1-6. Copyright © 1984 Massachusetts Medical Society. All rights reserved.)

ducts, resulting in an exudative vaginal discharge or an abscess.

Infections in teenage girls are often asymptomatic, just as they are in teenage boys. Rates of infection vary according to region of the country and other factors. At pelvic examination, clues to infection are the presence of mucopurulent discharge from the cervical os (known as *mucopus*; see Figure 330-2), cervical erythema, and friability. Gram stain of cervical tissue will reveal the presence of 10 to 30 polymorphonuclear white blood cells (WBCs) per oil-immersion field. However, many patients lack any symptoms or signs of infection. Given the high prevalence of infection among adolescents and young adults and the serious morbidity associated with untreated disease, every sexually active adolescent and young adult female aged 25 or younger should be screened for chlamydia at least annually; some researchers suggest testing twice a year, especially in areas where the prevalence of infection is high. Screening programs for chlamydia have been shown to reduce the incidence of PID.

The CDC recommends NAAT as the diagnostic assay of choice for the detection of chlamydia infection. A comparison of the sensitivity and specificity of the various diagnostic tests for chlamydia infection can be found at [www.prevent.org/data/files/ncc/research%20brief%201%20std%20testing.pdf](http://www.prevent.org/data/files/ncc/research%20brief%201%20std%20testing.pdf). Box 330-4 lists drugs and dose information for treatment.

As with treatment for any STI, the patient's abstinence from intercourse is imperative until therapy is complete and the patient's partner is notified and treated. Reinfection rates among teenagers treated for chlamydia are lower if the patient knows for certain

that her partner was treated. Another strategy to reduce the burden of reinfection is expedited partner therapy (EPT), in which a physician treats the sex partner(s) of the patient without first requiring a clinical evaluation. EPT has been shown in some studies to reduce the rates of persistent or recurrent gonorrhea and chlamydia infection among heterosexual individuals. Before using EPT, physicians should become familiar with state and local laws governing its use. Short-term complications of chlamydial infection include epididymitis and PID; long-term complications include reactive arthritis and the sequelae of PID. Although infection with chlamydia is not an independent risk factor for the development of cervical dysplasia, it may play some role. An untreated, infected woman can pass the infection to her infant through colonization during birth.

### ***Neisseria gonorrhoeae***

Infection with *N gonorrhoeae* produces a constellation of symptoms similar to that produced by *C trachomatis*. In general, men who are symptomatic with gonococcal infection tend to have more pronounced symptoms (more severe dysuria and a greater amount of and more purulent discharge), and they usually seek health care more quickly than those infected with *C trachomatis*. However, many patients have no symptoms at all. In a recent study of young adult men, the overall prevalence was 0.4%, with a range up to 2.4%; more than 95% were asymptomatic. Among young adult women, the overall rate of infection was 0.4%, (range up to 1.9%); almost 87% were asymptomatic. The gonococcus can cause pharyngitis and proctitis;

**BOX 330-4 Treatment for Sexually Transmitted Infections****CHLAMYDIAL INFECTION IN ADOLESCENTS AND ADULTS****Treatment**

Treatment of infected patients prevents transmission to sex partners, and, for infected pregnant women, treatment usually prevents transmission of *C trachomatis* to infants during birth. Treatment of sex partners helps prevent reinfection of the index patient and infection of other partners.

Coinfection with *C trachomatis* often occurs among patients who have gonococcal infection; therefore, presumptive treatment of such patients for chlamydia is appropriate (see Dual Therapy for Gonococcal and Chlamydial Infections, later in this box). The following recommended treatment regimens and alternative regimens cure infection and usually relieve symptoms.

**Recommended Regimens**

Azithromycin 1 g PO in a single dose OR

Doxycycline 100 mg PO twice daily for 7 days

**Alternative Regimens**

Erythromycin base 500 mg PO 4 times daily for 7 days OR  
Erythromycin ethylsuccinate 800 mg PO 4 times daily for 7 days OR

Levofloxacin 500 mg PO once daily for 7 days OR

Ofloxacin 300 mg PO twice daily for 7 days

A meta-analysis of 12 randomized clinical trials of azithromycin versus doxycycline demonstrated that the 2 treatments were equally efficacious, with cure rates of 97% and 98%, respectively. These investigations were conducted primarily in populations in which follow-up was encouraged, adherence to a 7-day regimen was effective, and culture or enzyme-linked immunoabsorbent assays (rather than nucleic acid amplification tests [NAAT]) were used to determine microbiological outcome. More recent studies have raised concern about the efficacy of azithromycin for rectal *C trachomatis* infection. Although the clinical significance of oropharyngeal *C trachomatis* infection is unclear and routine oropharyngeal screening for *C trachomatis* is not recommended, available evidence suggests oropharyngeal *C trachomatis* can be sexually transmitted to genital sites; therefore, *C trachomatis* detected from an oropharyngeal specimen should be treated with azithromycin or doxycycline.

In populations with erratic health care-seeking behavior, poor compliance with treatment, or unpredictable follow-up, azithromycin may be more cost effective than doxycycline because it offers single-dose, directly observed therapy. Erythromycin might be less efficacious than both azithromycin and doxycycline, mainly because the gastrointestinal side effects frequently discourage patients from complying with this regimen. Levofloxacin and ofloxacin are effective treatment alternatives but are more expensive and offer no advantage with regard to the dose regimen. Other quinolones either are not reliably effective against chlamydial infection or have not been adequately evaluated.

Azithromycin should always be available to treat patients for whom compliance with multiday dosing is questionable. To maximize compliance with recommended therapies, medications for chlamydial infections

should be dispensed on site, and the first dose should be directly observed. To minimize further transmission of infection, patients treated for chlamydia should be instructed to abstain from sexual intercourse for 7 days after single-dose therapy or until completion of a 7-day regimen. Patients should also be instructed to abstain from sexual intercourse until all of their sex partners are treated to minimize the risk for reinfection.

**Follow-up**

Except for pregnant women, patients do not need to be retested for chlamydia after completing treatment with the recommended or alternative regimens unless compliance is in question, symptoms persist, or reinfection is suspected. False-negative results might occur because of small numbers of chlamydial organisms. In addition, NAAT conducted less than 3 weeks after completion of therapy for patients who were treated successfully might yield false-positive results because of the continued presence of nonviable organisms.

Studies have demonstrated high rates of infection among women retested several months after treatment, presumably because of reinfection by an untreated sex partner; infection from a new partner with chlamydia is also possible. Repeat infections confer an increased risk for pelvic inflammatory disease (PID) and other complications. Chlamydia-infected men and women should be retested approximately 3 months after treatment regardless of whether they think their sex partner(s) have been treated. If retesting at 3 months is not possible, physicians should retest whenever persons next seek medical care within the next 12 months following the initial treatment.

**GONOCOCCAL INFECTION IN ADOLESCENTS AND ADULTS****Dual Therapy for Gonococcal and Chlamydial Infections**

Patients infected with *N gonorrhoeae* often are coinfecting with *C trachomatis*; this finding led to the recommendation that patients treated for gonococcal infection also be treated routinely with a regimen effective against uncomplicated genital *C trachomatis* infection. Because most gonococci in the United States are susceptible to doxycycline and azithromycin, routine co-treatment might hinder the development of antimicrobial-resistant *N gonorrhoeae*. Limited data suggest that dual therapy with azithromycin might also enhance the efficacy of oral cephalosporins if used to treat pharyngeal gonococcal infection. Because of the high sensitivity of NAAT for chlamydial infection, patients with a negative chlamydial NAAT result at the time of treatment for gonorrhea do not need to be treated for chlamydia as well. However, if test results for chlamydia are not available or a non-NAAT was negative for chlamydia, then patients should be treated for both chlamydia and gonorrhea.

**Antimicrobial-resistant *N gonorrhoeae***

Gonorrhea treatment is complicated by the ability of this organism to develop resistance to antimicrobial therapies. Quinolone-resistant strains are widespread throughout the United States and the world, and as of 2007 this class of antibiotics is no longer recommended for treatment of gonococcal infection (and associated

**BOX 330-4 Treatment for Sexually Transmitted Infections—cont'd**

conditions such as PID) in the United States. The proportion of isolates in the Centers for Disease Control and Prevention (CDC) Gonococcal Isolate Surveillance Project demonstrating decreased susceptibility to ceftriaxone or cefixime has remained very low. Most treatment failures from use of oral cephalosporins have been reported from Asian countries; hence, physicians should ask patients testing positive for gonorrhea about recent travel to and sexual activity in these countries.

**UNCOMPLICATED GONOCOCCAL INFECTIONS OF THE CERVIX, URETHRA, AND RECTUM****Recommended Regimen**

Ceftriaxone 250 mg IM in a single dose  
PLUS

Azithromycin 1 g orally in a single dose

**Alternative Regimens**

If ceftriaxone is not available:

Cefixime 400 mg orally in a single dose  
PLUS

Azithromycin 1 g PO in a single dose

To maximize compliance with recommended regimens, medications for gonococcal infections should be dispensed on site. Ceftriaxone in a single injection of 250 mg provides sustained, high bactericidal levels in the blood. Extensive clinical experience indicates that ceftriaxone is safe and effective for the treatment of uncomplicated gonorrhea at all anatomic sites, curing 99.2% of uncomplicated urogenital and anorectal and 98.9% of pharyngeal infections in published clinical trials. The 250-mg (rather than the 125-mg) dose of ceftriaxone is now recommended given (1) the increasingly wide geographic distribution of isolates demonstrating decreased susceptibility to cephalosporins *in vitro*, (2) reports of ceftriaxone treatment failures, (3) improved efficacy of ceftriaxone 250 mg to treat pharyngeal infection (which often goes unrecognized), and (4) the utility of having a simple and consistent recommendation for treatment regardless of anatomic site.

The 400-mg oral dose of cefixime does not provide as high nor as sustained a bactericidal level as that provided by the 250-mg dose of ceftriaxone. In published clinical trials, the 400-mg dose cured 97.5% of uncomplicated urogenital and anorectal and 92.3% of pharyngeal gonococcal infections. Although cefixime can be given orally, this advantage is offset by the limited efficacy of cefixime for treating pharyngeal gonococcal infection. Ongoing use of cefixime may hasten the development of resistance to ceftriaxone. The use of ceftriaxone in conjunction with azithromycin may potentially slow the emergence of resistance to cephalosporins. Other single-dose cephalosporin regimens that are safe and highly effective for uncomplicated urogenital and anorectal gonococcal infections include ceftizoxime 500 mg IM, cefoxitin 2 g administered IM with 1 g probenecid administered orally, and cefotaxime 500 mg IM. None of these injectable cephalosporins offers any advantage over ceftriaxone for urogenital infection, and efficacy for pharyngeal infection is less certain. Information about other alternative treatment regimens

for gonococcal infections can be found in the 2015 Sexually Transmitted Diseases Treatment Guidelines, available at [www.cdc.gov/std/tg2015/default.htm](http://www.cdc.gov/std/tg2015/default.htm).

**UNCOMPLICATED GONOCOCCAL INFECTIONS OF THE PHARYNX**

Most gonococcal infections of the pharynx are asymptomatic. Gonococcal infections of the pharynx are more difficult to eradicate than infections at urogenital and anorectal sites. Few antimicrobial regimens, including those involving oral cephalosporins, can reliably cure greater than 90% of gonococcal pharyngeal infections. Physicians should ask about oral sexual exposure; patients who report this sexual behavior should be treated with a regimen that has acceptable activity against pharyngeal infection. Although chlamydial coinfection of the pharynx is unusual, coinfection at genital sites sometimes occurs; therefore, treatment for both gonorrhea and chlamydia is suggested.

**Recommended Regimen**

Ceftriaxone 250 mg IM in a single dose PLUS  
Azithromycin 1 g PO in a single dose

**Follow-up**

Test of cure is not indicated for patients with uncomplicated gonorrhea treated with any of the recommended or alternative regimens. Patients who have symptoms that persist after treatment should be evaluated with culture for *N gonorrhoeae*, and any gonococci isolated should be tested for antimicrobial susceptibility. Persistent urethritis, cervicitis, or proctitis also might be caused by *C trachomatis* or other organisms.

*N gonorrhoeae* infection is prevalent among patients who have been diagnosed with and treated for gonorrhea in the preceding several months. Most of these infections are caused by reinfection rather than treatment failure. Physicians should advise all patients with gonorrhea to be retested 3 months after treatment, and those not seeking retesting within 3 months should be tested when they next seek medical care in the ensuing 12 months.

**DISSEMINATED GONOCOCCAL INFECTION**

DGI results from gonococcal bacteremia. DGI often results in petechial or pustular acral skin lesions, asymmetrical arthralgia, tenosynovitis, or septic arthritis. The infection is complicated occasionally by perihepatitis, and rarely by endocarditis or meningitis. Some strains of *N gonorrhoeae* that cause DGI may cause minimal genital inflammation. No recent studies have been published on the treatment of DGI.

**Treatment**

Hospitalization is recommended for initial therapy, especially for patients who cannot be relied on to comply with treatment, for those in whom the diagnosis is uncertain, and for those who have purulent synovial effusions or other complications. Patients should be examined for clinical evidence of endocarditis and meningitis. Patients treated for DGI should be treated presumptively for concurrent *C trachomatis* infection.

*Continued*

**BOX 330-4 Treatment for Sexually Transmitted Infections—cont'd****Recommended Regimen**

Ceftriaxone 1 g IM or IV every 24 hours PLUS azithromycin 1 g PO in a single dose

**Alternative Regimens**

Cefotaxime 1 g IV every 8 hours OR

Ceftizoxime 1 g IV every 8 hours

PLUS

Azithromycin 1 g PO in a single dose

All regimens should be continued for 24 to 48 hours after improvement begins, at which time therapy may be switched to another oral agent guided by antimicrobial testing to complete at least 1 week of antimicrobial therapy. No treatment failures have been reported with the recommended regimens.

**HUMAN PAPILLOMAVIRUS INFECTION—GENITAL WARTS****Treatment**

The primary goal of treating visible genital warts is the removal of the warts. In most patients, treatment can induce wart-free periods. Left untreated, visible warts may resolve, may remain unchanged, or may increase in size or number. Current evidence indicates that presently available treatments likely reduce, but probably do not eradicate, human papillomavirus (HPV) infectivity. Whether the reduction in HPV viral DNA resulting from treatment affects future transmission remains unclear. No evidence links the presence of genital warts or their treatment with the development of cervical cancer.

**Regimens**

Treatment of genital warts should be guided by the preference of the patient, the available resources, and the experience of the primary care physician. No definitive evidence has been found to suggest that any of the available treatments is superior to other treatments, and no single treatment is ideal for all patients or all warts. Because of the uncertainty regarding the effect of treatment on future transmission of HPV and the possibility of spontaneous resolution, an acceptable alternative for some people is to forego treatment and wait for spontaneous resolution.

Factors that influence selection of treatment include wart size and number, anatomic site of infection, wart morphology, patient preference, cost of treatment, convenience, adverse effects, and physician experience. In general, warts on moist surfaces or in intertriginous areas respond best to topical treatment. The treatment method should be changed if the patient has not improved substantially after a complete course of treatment or if side effects are severe. Most genital warts respond within 3 months of therapy.

The available treatments for visible genital warts are patient-applied therapies (ie, podofilox, imiquimod) and physician-administered therapies (ie, cryotherapy, trichloroacetic acid [TCA], bichloroacetic acid [BCA], interferon, surgery). Having a treatment plan or protocol has been associated with improved clinical outcomes. The response to treatment and its side effects should be evaluated throughout the course of therapy.

Complications rarely occur if treatments for warts are employed properly. Patients should be warned that persistent hypo- or hyperpigmentation is common with ablative modalities. Depressed or hypertrophic scars are rare but can occur, especially if the patient has had insufficient time to heal between treatments. Treatment can result rarely in disabling chronic pain syndromes (eg, vulvodynia or analdynia, hyperesthesia of the treatment site) or, in the case of rectal warts, painful defecation or fistulas. A limited number of case reports of severe systemic effects from podophyllin resin and interferon have been documented.

Patient-applied treatments are preferred by some patients because they can be administered in the privacy of the patient's home. For these treatments to be effective, patients must be able to comply with the treatment regimen and be able to identify and reach all genital warts. Follow-up visits are not required for individuals using patient-applied therapy.

**Recommended Regimens for External Anogenital Warts (i.e., penis, groin, scrotum, vulva, perineum, external anus, and perianus)**

Many persons with external anal warts also have intra-anal warts. Thus, persons with external anal warts might benefit from an inspection of the anal canal by digital exam, standard anoscopy, or high-resolution anoscopy.

**Patient Applied**

**Imiquimod 3.75% or 5% cream:** Patients should apply imiquimod cream once daily at bedtime, 3 times a week for up to 16 weeks. The treatment area should be washed with soap and water 6 to 10 hours after the application. Local inflammatory reactions, including redness, irritation, induration, ulcerations or erosions, and vesicles occur commonly with use of imiquimod, and hypopigmentation has been described. Imiquimod may weaken condoms and vaginal diaphragms. Data from studies of human subjects are limited regarding use of imiquimod in pregnancy, but animal data suggest that this therapy poses low risk.

OR

**Podofilox 0.5% solution or gel:** Patients should apply podofilox solution with a cotton swab, or podofilox gel with a finger, to visible genital warts twice daily for 3 days, followed by 4 days without therapy. This cycle may be repeated as necessary for a total of 4 cycles. The total wart area treated should not exceed 10 cm<sup>2</sup>, and the total volume of podofilox should not exceed 0.5 mL per day. If possible, the primary care physician should apply the initial treatment to demonstrate the proper application technique and identify which warts should be treated. Mild to moderate pain or local irritation might develop after treatment. *The safety of podofilox during pregnancy has not been established.*

OR

**Sinecatechins 15% ointment:** Sinecatechin ointment should be applied 3 times daily (0.5 cm strand of ointment to each wart) using a finger to ensure complete coverage until complete clearance of warts. Treatment should not be continued for longer than 16 weeks. The medication should not be washed off after application, and all sexual activity should be avoided while the

**BOX 330-4 Treatment for Sexually Transmitted Infections—cont'd**

ointment is on the skin. Side effects include erythema, pruritus, burning, pain, ulceration, edema, induration, and vesicular rash. Sinecatechins may weaken condoms and diaphragms. This treatment is not recommended for HIV-positive or immunocompromised individuals or for persons with genital herpes. *The safety of sinecatechins during pregnancy is unknown.*

**Physician Administered****Cryotherapy with liquid nitrogen or cryoprobe:**

Repeat applications every 1 to 2 weeks. Pain after application of the liquid nitrogen, followed by necrosis and even blistering, is common. Local anesthesia (topical or injected) might facilitate treatment if warts are present in many areas or if the area of warts is large.

OR

**Surgical removal either by tangential scissor excision, tangential shave excision, curettage, or electrosurgery**

OR

**Trichloroacetic acid (TCA) or bichloroacetic acid (BCA) 80% to 90%:** Apply a small amount only to warts and allow to dry (at which time a white frosting develops) before the patient sits or stands up. If pain is intense, the acid can be neutralized with soap or sodium bicarbonate. Powder with talc, sodium bicarbonate (baking soda), or liquid soap to remove unreacted acid if an excess amount is applied. Repeat weekly if necessary.

Because of the shortcomings of available treatments, some physicians employ combination therapy (the simultaneous use of 2 or more modalities on the same wart at the same time). Data are limited regarding the efficacy or risk of complications associated with use of such combinations.

**Alternative Treatments**

Intralesional interferon OR

Photodynamic therapy OR

Topical cidofovir

**Recommended Regimens for Urethral Meatus Warts**

Cryotherapy with liquid nitrogen

OR

Surgical removal

**Recommended Regimens for Cervical Warts**

Cryotherapy with liquid nitrogen

OR

Surgical removal

OR

TCA or BCA 80% to 90% solution

For women who have exophytic cervical warts, high-grade squamous intraepithelial lesions must be excluded before treatment is begun. Management of exophytic cervical warts should include consultation with a specialist.

**Recommended Regimens for Vaginal Warts**

Cryotherapy with liquid nitrogen. The use of a cryoprobe in the vagina is not recommended because of the risk for vaginal perforation and fistula formation.

OR

Surgical removal

OR

TCA or BCA 80% to 90% solution

**Recommended Regimens for Urethral Meatus Warts**

Cryotherapy with liquid nitrogen

OR

Podophyllin 10% to 25% in compound tincture of benzoin. The treatment area must be dry before contact with normal mucosa. Podophyllin can be applied weekly if necessary. *The safety of podophyllin during pregnancy has not been established.* Data are limited on the use of podofilox and imiquimod for the treatment of distal meatal warts.

**Recommended Regimens for Intra-anal Warts**

Cryotherapy with liquid nitrogen

OR

Surgical removal

OR

TCA or BCA 80% to 90%

Intra-anal warts should be managed in consultation with a specialist.

**Genital Herpes Simplex Virus Infection**

Genital herpes is a chronic, lifelong viral infection. Most cases of recurrent genital herpes are caused by herpes simplex virus type 2 (HSV-2). An increasing proportion of anogenital herpetic infections have been attributed to HSV-1 infection, especially young women and men who have sex with men. Most people with HSV-2 infection have not been diagnosed; many of them have mild or unrecognized disease but shed virus intermittently in the genital tract. The majority of genital herpes infections are transmitted by people who do not know they are infected or who are asymptomatic at the time transmission occurs.

Clinical diagnosis of genital herpes is challenging. Recurrences and subclinical shedding are much more common with genital HSV-2 compared to HSV-1 infection. A patient's prognosis and the type of counseling needed depend on whether the infection is caused by HSV-1 or HSV-2. Therefore, the clinical diagnosis should be confirmed by type-specific laboratory testing.

**First Clinical Episode of Genital Herpes**

Many patients with first-episode herpes have mild clinical manifestations but later develop severe or prolonged symptoms. Therefore, patients with initial genital herpes should receive antiviral therapy.

**Recommended Regimens**

Acyclovir 400 mg PO 3 times daily for 7 to 10 days

OR

Acyclovir 200 mg PO 5 times daily for 7 to 10 days

OR

Valacyclovir 1 g PO 2 times daily for 7 to 10 days

Continued

**BOX 330-4 Treatment for Sexually Transmitted Infections—cont'd**

OR

Famciclovir 250 mg PO 3 times daily for 7 to 10 days  
Treatment may be extended if healing is incomplete after 10 days of therapy.

**ESTABLISHED HERPES SIMPLEX VIRUS TYPE 2 INFECTION**

Most patients with symptomatic, first-episode genital HSV-2 infection will have recurrent episodes of genital lesions; recurrences are less frequent after initial genital HSV-1 infection. Intermittent asymptomatic shedding occurs in persons with genital HSV-2 infection, even in those with longstanding or clinically silent infection. Antiviral therapy for recurrent disease can be administered either episodically to ameliorate or shorten the duration of lesions or continuously as suppressive therapy to reduce the frequency of recurrences. Many persons, even those with mild or infrequent outbreaks, benefit from antiviral therapy; therefore, options for treatment should be discussed. Some persons may prefer suppressive therapy, which has the additional advantage of decreasing the risk of genital HSV-2 transmission to susceptible partners.

Daily suppressive therapy reduces the frequency of genital herpes recurrences by 70% to 80% in patients who have frequent recurrences (ie, 6 or more recurrences per year). Treatment is also effective in patients with less frequent recurrences. Safety and efficacy have been documented among patients receiving daily therapy with acyclovir for as long as 6 years and with valacyclovir or famciclovir for 1 year. The frequency of recurrences diminishes over time in many patients, and the patient's psychological adjustment to disease might change. Therefore, periodically (eg, once a year), physicians should discuss the need to continue suppressive therapy with the patient.

Suppressive therapy with valacyclovir 500 mg daily decreases the rate of HSV-2 transmission in discordant, heterosexual couples in which the source partner has a history of genital HSV-2 infection. Suppressive antiviral therapy probably reduces transmission when used by persons who have multiple partners (including men who have sex with men) and by those who are HSV-2 seropositive without a history of genital herpes.

**Recommended Regimens for Daily Suppressive Therapy**

Acyclovir 400 mg PO twice daily OR

Valacyclovir 500 mg once daily OR

Valacyclovir 1 g PO once daily

Famciclovir 250 mg PO twice daily

Valacyclovir 500 mg once daily may be less effective than other valacyclovir or acyclovir dosing regimens in patients who have very frequent recurrences (ie, at least 10 episodes per year).

**Episodic Therapy for Recurrent Genital Herpes**

Effective episodic therapy of recurrent herpes requires initiation of therapy within 1 day of lesion onset or during the prodrome that precedes some outbreaks. The patient should be provided with a supply of drug or a prescription for the medication with instructions to initiate treatment as soon as symptoms begin.

**Recommended Regimens**

Acyclovir 400 mg PO 3 times daily for 5 days OR

Acyclovir 800 mg PO twice daily for 5 days OR

Acyclovir 800 mg PO 3 times daily for 2 days OR

Valacyclovir 500 mg PO twice daily for 3 days OR

Valacyclovir 1 g PO once daily for 5 days OR

Famciclovir 125 mg PO twice daily for 5 days OR

Famciclovir 1,000 mg PO twice daily for 1 day OR

Famciclovir 500 mg PO once, followed by 250 mg twice daily for 2 days

**PRIMARY AND SECONDARY SYPHILIS****Treatment**

Parenteral penicillin G is the preferred drug for treatment of all stages of syphilis. The preparation used (ie, benzathine, aqueous procaine, aqueous crystalline), the dose, and the length of treatment all depend on the stage and clinical manifestations of the disease.

**Recommended Regimen for Adults**

Adults who have primary or secondary syphilis should be treated with benzathine penicillin G 2.4 million units IM in a single dose. HIV-infected patients with primary and secondary syphilis should also receive this dose; available data do not suggest that higher doses or use of other antibiotics result in enhanced efficacy.

**Recommended Regimen for Children**

After the newborn period ( $\geq 1$  month), children with syphilis should have a cerebrospinal fluid (CSF) examination to detect asymptomatic neurosyphilis, and birth and maternal medical records should be reviewed to assess whether the child has congenital or acquired syphilis. Children with acquired primary or secondary syphilis should be evaluated for sexual abuse (including consultation with child-protection services) and treated using the following pediatric regimen:

Benzathine penicillin G 50,000 units/kg IM up to the adult dose of 2.4 million units in a single dose. (A child or adolescent weighing  $\geq 48$  kg would receive the adult dose.)

**Other Management Considerations**

All patients who have syphilis should be tested for HIV infection. In geographic areas in which the prevalence of HIV is high, patients who have primary syphilis should be retested for HIV after 3 months if the first HIV test result was negative.

Patients who have syphilis and symptoms or signs suggesting neurologic disease (eg, meningitis or hearing loss) or ophthalmic disease (eg, uveitis, iritis, neuroretinitis, optic neuritis) should be evaluated fully for neurosyphilis and syphilitic eye disease; this evaluation should include CSF analysis and otologic and ocular slit-lamp examinations. Such patients should be treated appropriately according to the results of this evaluation.

Invasion of CSF by *T pallidum* accompanied by CSF abnormalities is common among adults who have primary or secondary syphilis. However, neurosyphilis develops in only a few patients after treatment with the regimens described here. Therefore, unless clinical signs or symptoms of neurologic or ophthalmic involvement are present, lumbar puncture is not recommended for routine evaluation of patients who have primary or secondary syphilis.

**BOX 330-4 Treatment for Sexually Transmitted Infections—cont'd****Follow-up**

Treatment failure can occur with any regimen. However, assessing response to treatment is often difficult, and no definitive criteria for cure or failure have been established. Nontreponemal test titers may decline more slowly for patients who previously had syphilis. Patients should be re-examined clinically and serologically 6 and 12 months after treatment; more frequent evaluation may be prudent if follow-up is uncertain. HIV-infected patients should be evaluated clinically and serologically for treatment failure at 3, 6, 9, 12, and 24 months after therapy.

Patients who have signs or symptoms that persist or recur or who have a sustained fourfold increase in nontreponemal test titer for at least 2 weeks (ie, compared with the maximum or baseline titer at time of treatment) probably failed treatment or were reinfected. These patients should be retreated and reevaluated for HIV infection. Because treatment failure usually cannot be reliably distinguished from reinfection with *T pallidum*, a lumbar puncture also should be performed. HIV-infected patients who meet the criteria for treatment failure (signs or symptoms that persist or recur or persons who have a sustained fourfold increase in nontreponemal test titer) should be managed in the same manner as HIV-negative patients (CSF examination and retreatment as indicated below).

Although failure of nontreponemal test titers to decline fourfold within 6 to 12 months after therapy for primary or secondary syphilis may indicate treatment failure, clinical trial data have demonstrated that at least 15% of patients with early syphilis treated with recommended therapy will not achieve a 2-dilution decline in nontreponemal titer used to define response at 1 year after treatment. Persons whose titers do not decline should be re-evaluated for HIV infection. Optimal management of such patients is unclear. At a minimum, these patients should have additional clinical and serologic follow-up. If additional follow-up cannot be ensured, retreatment is recommended. Because treatment failure might be the result of unrecognized central nervous system infection, many specialists recommend CSF examination in such situations. When patients are retreated, weekly injections of benzathine penicillin G 2.4 million units IM for 3 weeks is recommended, unless CSF examination indicates that neurosyphilis is present.

**LATENT SYPHILIS**

Latent syphilis is defined as syphilis characterized by seroreactivity without other evidence of disease. Patients who have latent syphilis and who acquired syphilis within the preceding year are classified as having early latent syphilis. Patients can be diagnosed as having early latent syphilis if, within the year preceding the evaluation, they had (a) a documented seroconversion or fourfold or greater increase in titer of a nontreponemal test; (b) unequivocal symptoms of primary or secondary syphilis; (c) a sex partner documented to have primary, secondary, or early latent syphilis; or (d) reactive nontreponemal and treponemal tests with the only possible exposure occurring within the previous 12 months. Absent these conditions, an asymptomatic

person is considered to have late latent syphilis or syphilis of unknown duration. Nontreponemal serologic titers are usually higher during early latent syphilis than late latent syphilis. However, early latent syphilis cannot be reliably distinguished from late latent syphilis based solely on nontreponemal titers. All patients with latent syphilis should have thorough examination of all accessible mucosal surfaces (oral cavity, perineum, and vagina in women; perianal area and underneath the foreskin in uncircumcised men) to evaluate for internal mucosal lesions. All patients who have syphilis should be tested for HIV infection.

**Treatment**

Because latent syphilis is not transmitted sexually, the objective of treating patients with this stage of the disease is to prevent complications. Although clinical experience supports the effectiveness of penicillin in achieving this goal, limited evidence is available for guidance in choosing specific regimens.

**Recommended Regimens for Adults**

The following regimens are recommended for penicillin-nonallergic patients who have normal CSF examination (if performed).

Early latent syphilis: benzathine penicillin G 2.4 million units IM in a single dose. This same treatment is recommended for HIV-infected patients.

Late latent syphilis or latent syphilis of unknown duration: benzathine penicillin G 7.2 million units total, administered as 3 doses of 2.4 million units IM each at 1-week intervals. This same treatment regimen is recommended for HIV-infected patients.

**Recommended Regimens for Children**

After the newborn period (1 month of age or older), children with syphilis should have a CSF examination to exclude neurosyphilis. Birth and maternal records should be reviewed to assess whether the child has congenital or acquired syphilis. Older children with acquired latent syphilis should be evaluated as described for adults and treated using the following pediatric regimens. These regimens are for penicillin-nonallergic children with acquired syphilis who have normal CSF examination results.

Early latent syphilis: benzathine penicillin G 50,000 units/kg IM, up to the adult dose of 2.4 million units, in a single dose. (A child or adolescent who weighs  $\geq 48$  kg would receive the adult dose.)

Late latent syphilis or latent syphilis of unknown duration: benzathine penicillin G 50,000 units/kg IM, up to the adult dose of 2.4 million units, administered as 3 doses at 1-week intervals (total 150,000 units/kg up to the adult dose of 7.2 million units).

**Other Treatment Considerations**

Patients (including HIV-infected patients) with late latent syphilis who demonstrate any of the following should have a prompt CSF examination: (a) neurologic (auditory disease, cranial nerve dysfunction, acute or chronic meningitis, stroke, changes in mental status, loss of vibration sense) or ophthalmic signs or symptoms (iritis or uveitis), (b) evidence of active tertiary syphilis (eg, aortitis, gumma), or (c) treatment failure. If a patient misses

*Continued*

**BOX 330-4 Treatment for Sexually Transmitted Infections—cont'd**

a dose of penicillin in a course of weekly therapy for late syphilis, the appropriate course is unclear. Pharmacologic data suggest that if the interval between doses is 10 to 14 days, restarting injections may not be necessary.

**Follow-up**

Quantitative nontreponemal serologic tests should be repeated at 6, 12, and 24 months. A CSF examination should be performed if (a) titers increase fourfold, (b) an initially high titer (at least 1:32) fails to decline at least fourfold (ie, 2 dilutions) within 12 to 24 months, or (c) signs or symptoms attributable to syphilis develop. In such circumstances, even if the CSF examination is negative, retreatment for latent syphilis should be initiated. HIV-infected patients should be evaluated clinically and serologically at 6, 12, 18, and 24 months after therapy. If at any time clinical symptoms develop or nontreponemal test titers rise fourfold, a CSF examination should be performed and treatment administered accordingly. If during 12 to 24 months the nontreponemal test does not decline fourfold, CSF examination should be strongly considered and treatment administered accordingly.

**PELVIC INFLAMMATORY DISEASE**

PID comprises a spectrum of inflammatory disorders of the upper female genital tract, including any combination of endometritis, salpingitis, tubo ovarian abscess, and pelvic peritonitis. Sexually transmitted organisms, especially *N gonorrhoeae* and *C trachomatis*, are implicated in many cases; however, microorganisms that comprise the vaginal flora (eg, anaerobes, *Gardnerella vaginalis*, *Haemophilus influenzae*, enteric Gram-negative rods, and *Streptococcus agalactiae*) also have been associated with PID. In addition, cytomegalovirus (CMV), *Mycoplasma hominis*, *Ureaplasma urealyticum*, and *Mycoplasma genitalium* might be associated with some cases of PID. All women who are diagnosed with acute PID should be tested for *N gonorrhoeae* and *C trachomatis* and screened for HIV infection.

**Treatment**

PID treatment regimens must provide empiric, broad-spectrum coverage of likely pathogens. All regimens should be effective against *N gonorrhoeae* and *C trachomatis*, because negative endocervical screening for these organisms does not preclude upper reproductive tract infection. The need to eradicate anaerobes from women who have PID has not been demonstrated definitively. Anaerobic bacteria have been isolated from the upper reproductive tract of women who have PID, and data from in vitro studies have revealed that anaerobes such as *Bacteroides fragilis* can cause tubal and epithelial destruction. In addition, bacterial vaginosis also is diagnosed in many women who have PID. Until treatment regimens that do not adequately cover these microbes have been shown to prevent sequelae as successfully as the regimens that are effective against these microbes, the use of regimens with anaerobic activity should be considered. Treatment should be initiated as soon as the presumptive diagnosis has been made, because prevention of long-term sequelae is dependent on early administration of appropriate antibiotics. When selecting a treatment regimen, physicians should consider

availability, cost, patient acceptance, and antimicrobial susceptibility.

Evidence is insufficient to recommend the removal of an intrauterine device in women diagnosed with acute PID. However, caution should be exercised if the intrauterine device remains in place and close follow-up is mandatory. Comprehensive observational and controlled studies demonstrate that HIV-infected women with PID have similar symptoms when compared with uninfected controls, except they were more likely to have a tubo-ovarian abscess. Both groups responded equally well to standard parenteral and oral antibiotic regimens. Regardless of the data, whether or not immunodeficient HIV-infected women with PID require more aggressive treatment is uncertain.

**Parenteral Treatment**

For women with mild to moderate PID, parenteral therapy and oral therapy seem to have similar clinical efficacy. Many randomized trials have demonstrated the efficacy of both parenteral and oral regimens. Clinical experience should guide decisions regarding transition to oral therapy, which usually can be initiated within 24 to 48 hours of clinical improvement. At least 24 hours of direct inpatient observation is recommended for patients who have tubo-ovarian abscess.

**Recommended Parenteral Regimens**

Cefotetan 2 g IV every 12 hours

PLUS

Doxycycline 100 mg orally or IV every 12 hours

OR

Cefoxitin 2 g IV every 6 hours PLUS

Doxycycline 100 mg PO or IV every 12 hours

OR

Clindamycin 900 mg IV every 8 hours

PLUS

Gentamicin loading dose IV or IM (2 mg/kg) followed by a maintenance dose (1.5 mg/kg) every 8 hours.

Single daily dosing (3–5 mg/kg) can be substituted.

Because of pain associated with infusion, doxycycline should be administered orally when possible, even when the patient is hospitalized. Oral and IV administration of doxycycline provide similar bioavailability. Although use of a single daily dose of gentamicin has not been evaluated for the treatment of PID, it is efficacious in analogous situations.

Parenteral therapy may be discontinued 24 to 48 hours after a patient improves clinically, but oral therapy with doxycycline (100 mg twice/day) should continue for a total of 14 days. When tubo-ovarian abscess is present, clindamycin or metronidazole with doxycycline can be used for continued therapy rather than doxycycline alone, because this regimen provides more effective anaerobic coverage.

Clinical data are limited regarding the use of other second- or third-generation cephalosporins (eg, ceftizoxime, cefotaxime, ceftriaxone), which also might be effective therapy for PID and might replace cefotetan or cefoxitin. However, they are less active than cefotetan or cefoxitin against anaerobic bacteria.

**BOX 330-4 Treatment for Sexually Transmitted Infections—cont'd**

Parenteral therapy may be discontinued 24 hours after a patient improves clinically; continuing oral therapy should consist of doxycycline 100 mg PO twice daily or clindamycin 450 mg PO 4 times daily to complete a total of 14 days of therapy. When tubo-ovarian abscess is present, clindamycin should be continued rather than doxycycline because clindamycin provides more effective anaerobic coverage.

**Alternative Parenteral Regimens**

Ampicillin/sulbactam 3 g IV every 6 hours PLUS

Doxycycline 100 mg PO or IV every 12 hours

Ampicillin/sulbactam plus doxycycline is effective against *C trachomatis*, *N gonorrhoeae*, and anaerobes in women with tubo-ovarian abscess. One trial demonstrated high short-term clinical cure rates with azithromycin, either as monotherapy for 1 week (500 mg IV for 1 or 2 doses followed by 250 mg PO for 5 to 6 days) or combined with a 12-day course of metronidazole.

**Intramuscular/Oral Treatment**

Intramuscular/oral outpatient therapy can be considered for women with mild-to-moderately severe acute PID, given that the clinical outcomes among women treated with these therapies are similar to those treated with parenteral therapy. Patients who do not respond to IM/oral therapy within 72 hours should be re-evaluated to confirm the diagnosis and should be administered parenteral therapy.

**Recommended Intramuscular/Oral Regimens**

Ceftriaxone 250 mg IM in a single dose

PLUS

Doxycycline 100 mg PO twice daily for 14 days

WITH\* OR WITHOUT

Metronidazole 500 mg PO twice daily for 14 days

OR

Cefoxitin 2 g IM in a single dose and probenecid 1 g PO administered concurrently in a single dose

PLUS

Doxycycline 100 mg PO twice daily for 14 days

WITH\* OR WITHOUT

Metronidazole 500 mg PO twice daily for 14 days

OR

Other parenteral third-generation cephalosporin (eg, ceftizoxime or cefotaxime)

PLUS

Doxycycline 100 mg PO twice daily for 14 days

WITH\* OR WITHOUT

Metronidazole 500 mg PO twice daily for 14 days (\*The recommended third-generation cephalosporins are limited in their anaerobic coverage; therefore, until it is known that extended anaerobic coverage is not important for treatment of acute PID, the addition of metronidazole to these treatment regimens should be considered.)

These regimens provide coverage against frequent etiologic agents of PID, but the optimal choice of a cephalosporin is unclear. Cefoxitin has better anaerobic coverage than ceftriaxone, and in combination with

probenecid and doxycycline has been effective in short-term clinical response in women with PID. Ceftriaxone has better coverage against *N gonorrhoeae*. Metronidazole will also effectively treat bacterial vaginosis, which is often associated with PID.

**Alternative Oral Regimens**

Azithromycin has shown short-term effectiveness in at least one clinical trial (500 mg IV daily for 1–2 doses, followed by 250 mg orally daily for 12–14 days) or in combination with metronidazole; in another study, it was effective when 1 g orally once per week for 2 weeks was used in combination with ceftriaxone 250 mg IM in a single dose. Concomitant use of metronidazole for anaerobic coverage should be considered.

As a result of the emergence of quinolone-resistant *N gonorrhoeae*, regimens that include a quinolone agent are no longer recommended for treatment of PID. If parenteral cephalosporin therapy is not feasible and the community prevalence and individual risk for gonorrhea are low, and follow-up is likely, then use of fluoroquinolones (levofloxacin 500 mg PO once daily or ofloxacin 400 mg PO twice daily or moxifloxacin 400 mg orally once daily for 14 days) with metronidazole (500 mg PO twice daily for 14 days) can be considered. Tests for gonorrhea must be performed before instituting therapy and the patient managed as follows:

- If culture for gonorrhea is positive, treatment should be based on the results of antimicrobial susceptibility.
- If the isolate is determined to be quinolone-resistant *N gonorrhoeae*, or if antimicrobial susceptibility cannot be assessed (if only NAAT testing is available), consultation with an infectious disease specialist is recommended.

**Follow-up**

Patients should demonstrate substantial clinical improvement (defervescence, reduction in direct or rebound abdominal tenderness, reduction in uterine, adnexal, and cervical motion tenderness) within 72 hours of initiation of therapy. Patients who do not improve within 72 hours usually require hospitalization, additional diagnostic tests, and surgical intervention.

Assessment of the antimicrobial regimen and diagnostics (including the consideration of diagnostic laparoscopy for alternative diagnoses) is recommended in women without clinical improvement. Women with documented gonococcal or chlamydial infections have high rates of reinfection within 6 months of treatment. Repeat testing of these women is recommended 3 to 6 months after treatment, regardless of whether their sex partners were treated. All women with acute PID should be offered HIV testing. Male sex partners of women with PID should be examined and treated for gonorrhea and chlamydia if they had sexual contact with the patient during the 60 days preceding the patient's onset of symptoms. If the patient's last sexual intercourse was more than 60 days before onset of symptoms or diagnosis, the most recent partner should be treated.

**Epididymitis**

Empiric therapy is indicated before laboratory test results are available; all patients should therefore receive

*Continued*

**BOX 330-4 Treatment for Sexually Transmitted Infections—cont'd**

ceftriaxone plus doxycycline for the initial treatment of epididymitis. Additional therapy may include a quinolone if acute epididymitis is not caused by gonorrhea (results by a NAAT are negative) or if the infection is most likely caused by enteric organisms. *For men who are at risk for both sexually transmitted and enteric organisms (eg, men who report anal insertive intercourse), ceftriaxone and a fluoroquinolone are recommended.*

**Recommended Regimens**

**For acute epididymitis most likely caused by sexually transmitted chlamydia and gonorrhea:**

Ceftriaxone 250 mg IM in a single dose PLUS

Doxycycline 100 mg PO twice daily for 10 days

**For acute epididymitis most likely caused by sexually transmitted chlamydia and gonorrhea and enteric organisms (men who practice insertive anal sex):**

Ceftriaxone 250 mg IM in a single dose PLUS

Levofloxacin 500 mg PO once daily for 10 days OR

Ofloxacin 300 mg PO twice daily for 10 days

**For acute epididymitis most likely caused by enteric organisms:**

Levofloxacin 500 mg orally once daily for 10 days OR

Ofloxacin 300 mg orally twice a day for 10 days

**Proctitis, Proctocolitis, and Enteritis**

Sexually transmitted gastrointestinal syndromes include proctitis, proctocolitis, and enteritis. Evaluation should include appropriate diagnostic procedures (eg, anoscopy or sigmoidoscopy, stool examination, culture).

Proctitis is inflammation of the rectum (the distal 10 to 12 cm) that can be associated with anorectal pain, tenesmus, or rectal discharge. *N gonorrhoeae*, *C trachomatis* (including lymphogranuloma venereum [LGV] serovars), *T pallidum*, and HSV are the most common sexually transmitted pathogens involved. In patients coinfecting with HIV, herpes proctitis can be especially severe. Proctitis occurs predominantly among persons who participate in receptive anal intercourse.

Proctocolitis is associated with symptoms of proctitis, diarrhea or abdominal cramps (or both), and inflammation of the colonic mucosa extending to 12 cm above the anus. Fecal leukocytes may be detected on stool examination depending on the pathogen. Pathogenic organisms include *Campylobacter* species, *Shigella* species, *Entamoeba histolytica*, and LGV serovars of *C trachomatis*. CMV or other opportunistic agents can be involved in

immunosuppressed HIV-infected patients. Proctocolitis can be acquired by the oral route or by oral–anal contact, depending on the pathogen.

Enteritis usually results in diarrhea and abdominal cramping without signs of proctitis or proctocolitis; it occurs among persons whose sexual practices include oral–anal contact. In otherwise healthy patients, *G lamblia* is most commonly implicated. When outbreaks of gastrointestinal illness occur among social or sexual networks of men who have sex with men, physicians should consider sexual transmission as a mode of spread. Among HIV-infected patients, other infections that usually are not sexually transmitted may occur, including those caused by CMV, *Mycobacterium avium-intracellulare*, *Campylobacter* species, *Shigella* species, *Salmonella* species, *Cryptosporidium*, *Microsporidium*, and *Isospora*. Multiple stool examinations may be necessary to detect *Giardia*, and special stool preparations are required to diagnose cryptosporidiosis and microsporidiosis. Additionally, enteritis can be directly caused by HIV infection. When laboratory diagnostic capabilities are available, treatment should be based on the specific diagnosis.

**Treatment**

Acute proctitis of recent onset among persons who have recently practiced receptive anal intercourse is most often sexually transmitted. Such patients should be examined by anoscopy and should be evaluated for infection with HSV (polymerase chain reaction [PCR] or culture), *N gonorrhoeae* (NAAT or culture), *C trachomatis* (NAAT), and *T pallidum* (dark-field if available and serologic testing). A Gram-stained smear of any anorectal exudate should be examined for polymorphonuclear leukocytes. If the *C trachomatis* test on a rectal swab is positive, a molecular test PCR for LGV should be performed, if possible.

**Recommended Regimen**

Ceftriaxone 250 mg IM PLUS

Doxycycline 100 mg PO twice daily for 7 days

Bloody discharge, perianal ulcers, or mucosal ulcers among men who have sex with men (MSM) with acute proctitis and either a positive rectal chlamydia NAAT or HIV infection should be offered presumptive treatment for LGV (doxycycline 100 mg PO BID for 3 weeks).

Patients with suspected or documented herpes proctitis should be managed in the same manner as those with genital herpes.

Adapted from Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines, 2010. *MMWR* 2010;59 (No. RR-12):1–109 and Workowski KA, Bolan GA. Sexually transmitted diseases guidelines, 2015. *MMWR Recomm Rep*. 2015;64 (No. RR-3): 1–110. (In some cases, the author has edited the text to condense it.)

adolescent and young adult women may harbor the organism in the rectum even if they do not engage in anal intercourse.

The gonococcus can be grown from urethral or cervical discharge; from swabs of the vagina, cervix, urethra, pharynx, or rectum; and in many instances from urine sediment. In the past, the diagnosis of gonococcal infection rested on culture or on the classic findings of WBCs and gram-negative intracellular

diplococci in Gram stains of discharge or material obtained from a urethral swab. Even under ideal conditions, the organism can be difficult to grow, and physicians relying on culture should be familiar with the yield from the laboratory they use. In men, a typical Gram stain from a urethral discharge is diagnostic. For samples taken from women, sorting out gram-negative organisms that truly are intracellular versus those that may be overlying or near the cells

is more difficult. However, when at least 8 pairs of such diplococci are seen in at least 2 polymorphonuclear leukocytes, the culture will be positive 96% of the time.

As is the case with chlamydia, the CDC recommend use of NAAT for the detection of *N gonorrhoeae*. These tests are more sensitive than culture and have the added advantage of eliminating the need for pelvic examination or swabbing the urethral meatus to obtain specimens; instead, a urine specimen or vaginal swab can be used. Treatment regimens for uncomplicated gonococcal infections are listed in Box 330-4; as a result of increasing gonococcal resistance to fluoroquinolones, the CDC no longer recommends this class of antibiotics for treatment of gonococcal infection. In addition, because of concerns of increasing resistance of *N gonorrhoeae* to cephalosporins and the desire to have a single regimen to treat gonococcal infection at all sites, the CDC currently recommends 250 mg of ceftriaxone administered intramuscularly for treatment of uncomplicated gonococcal infections of the cervix, urethra, rectum, and pharynx. Because of the high likelihood of coinfection with chlamydia, treatment for gonorrhea must also include an effective regimen for *C trachomatis* unless a NAAT for chlamydia is known to be negative.

Gonorrhea also may produce epididymitis and PID. In addition and in contrast to chlamydia, the gonococcal organism has the capacity to become bloodborne and can lead to the so-called arthritis-dermatitis syndrome, or DGI. Approximately 1% to 3% of untreated patients develop DGI. Strains of *N gonorrhoeae* that lead to DGI characteristically tend to cause little in the way of genital symptoms. Typically (although not always), the patient develops fever and may have anorexia, malaise, or both. Skin lesions then appear, generally distributed on the extremities (arms more often than legs). The lesions appear as erythematous macules less than 5 mm in diameter; they become pustular and occasionally hemorrhagic or necrotic (Figure 330-3). They are most often noticed near the small joints of the hands and feet. Accompanying the dermatitis is a tenosynovitis that tends to occur over the extensor and flexor tendons of the hands and feet. During this early phase of the infection, especially if evaluated within 2 to 3 days of onset of symptoms, 25% to 50% of patients will have positive blood cultures.

In general, once the tenosynovitis and dermatitis clear, the patient develops polyarthralgia but usually seeks care only when an oligoarthritis develops. The knee is the joint most commonly infected, followed by the elbow, ankle, and small joints of the hands and feet. Hence, among adolescents, DGI should always be considered in the differential diagnosis of septic arthritis. Aspirates of joint fluid reveal the typical changes of septic arthritis, but joint fluid cultures are usually negative. Meningitis or endocarditis may also be present. Patients with DGI, especially those with arthritis, should be hospitalized—at least initially—for treatment (see Box 330-4).

### Human Papillomavirus (Genital Warts)

Infections with human papillomavirus (HPV) are the most prevalent STI in the United States. Such infections

**Figure 330-3** Disseminated gonococcal infection (DGI). If a gonorrhea infection is allowed to go untreated, the *N gonorrhoeae* can become disseminated throughout the body, forming lesions in extragenital locations. (Courtesy Red Book Online. [redbook.solutions.aap.org](http://redbook.solutions.aap.org))

have always drawn attention because they cause unsightly warts (condylomata acuminata), and because HPV infection represents the most common cause of an abnormal Papanicolaou test (Pap smear screening) among adolescent and young adult women. Current concerns about HPV focus on its role in the development of cervical neoplasia. HPV infection has been associated with more than 90% of cervical dysplasia worldwide.

More than 100 different types of HPV have been identified. The low-risk types 6 and 11 account for 97% of genital wart manifestations (external genital warts). Types 16, 18, 31, and 45 are responsible for approximately 80% of cervical cancers worldwide, with type 16 alone causing 40% to 60% of the disease burden. An individual can be infected with more than 1 type of HPV.

As with other STIs, infection rates among adolescents and young adults are high. The prevalence of cervical HPV infection among adolescents ages 12 to 21 is approximately 51% to 64%. Longitudinal studies of adolescent girls suggest that approximately 45% to 55% become infected over a 3-year period of observation.

Male adolescents constitute a significant reservoir of undetected HPV infection; rates of infection are highest among 20- to 29-year-old males. Few male partners of HPV-positive women have clinical evidence of warts, but when magnification and acetic acid soaks are used to produce the acetowhite changes seen in HPV-infected skin, far more men are found to be infected (see Figure 330-4). Almost all data regarding HPV among men are drawn from those aged 18 and older; little information exists about younger adolescent boys.

**Figure 330-4** Demonstration of subclinical lesions. **A**, Appearance of penis before application of acetic acid. **B**, Penis after 5-minute application of gauze soaked in 5% acetic acid. Note coalescing sheets (arrows) and discrete dots of acetowhite staining (inset). **C**, Magnified view of apparent subclinical human papillomavirus infection shown in panel B. (From Katelaris PM, Cossart YE, Rose BR, et al. *Human papilloma virus: the untreated male reservoir*. J Urol. 1988;140:300-305. Copyright © 1988, Elsevier, with permission.)

Visible warts usually develop within 6 weeks to 8 months after infection, but the incubation period may be even longer. The typical pedunculated wart with a keratotic and irregular surface is easy to recognize, but warts may also be flat and more difficult to detect. The use of a handheld magnifying glass or even a colposcope is extremely helpful. Among male adolescents, warts are usually seen on the penile shaft, prepuce, frenulum, corona, and glans, but they may also be present on the skin of the scrotum and the anus

(see Figure 330-5). The presence of anal warts is often associated with anal receptive intercourse, but warts in this location have been described in boys who deny this type of behavior. Occasionally, warts are seen at the urethral opening.

The posterior vaginal introitus, labia minora, and vestibule represent the most common sites of infection among female adolescents (see Figure 330-6); again, however, warts can be seen anywhere on the external or internal genitalia. Perianal warts can be seen even

**Figure 330-5** Morphology of macroscopic warts. **A**, Condylomata demonstrated by preputial retraction. **B**, Verrucous wart at penoscrotal junction. **C**, Small, flat warts (arrows) on distal third of penis. (From Katelaris PM, Cossart YE, Rose BR, et al. *Human papilloma virus: the untreated male reservoir*. J Urol. 1988;140:300–305. Copyright © 1988, Elsevier, with permission.)

**Figure 330-6** Condyloma acuminatum of the vulva appears as a polypoid mass with a keratotic fissured and irregular surface. (From Moscicki AB. *HPV infections: an old STD revisited*. Contemp Pediatr. 1989;6:24. Reprinted by permission.)

in women who have not had anal intercourse. Subclinical disease is most likely to occur on the cervix; the relatively large transformation zone of the maturing adolescent cervix affords a hospitable site of infection for the virus. Extensive disease should raise the possibility of underlying HIV infection.

A comprehensive cervical cytology screening program using the Pap smear to detect premalignant changes in the cervix (cervical intraepithelial neoplasia, usually caused by HPV infection) is a cornerstone of cervical cancer prevention efforts in the United States. However, the natural history of cervical intraepithelial neoplasia is not well understood, and HPV infection, which is widespread in young women, generally is self-limited. These observations, in concert with the knowledge that Pap smear screening in

adolescents can lead to additional unnecessary and expensive diagnostic testing that may be associated with psychologic and physiologic morbidity, have led to changes in Pap smear guidelines. The American Congress of Obstetricians and Gynecologists now recommends that Pap smear screening should not begin until age 21, regardless of the age of first intercourse. This recommendation does not apply to women with HIV infection, who are immunosuppressed, or who have had a previous diagnosis of cervical intraepithelial neoplasia (CIN2 or CIN3), or cancer. HPV DNA testing is also not indicated in women under the age of 21; it may be used in the management of women 21 and older with the diagnosis of atypical squamous cells of undetermined origin (ASCUS) on Pap smear, but repeating the Pap smear in one year is preferable.

A variety of treatments for genital warts exist, including those applied by physicians or by the patient (see Box 330-4); treatment is primarily directed toward symptomatic warts. Physicians who choose to treat genital warts should determine which technique is most suitable to their practice and become familiar with that technique; physicians should be knowledgeable about at least 1 physician-applied and 1 patient-applied regimen. Regardless of which approach is chosen, careful follow-up (initially at 1–2 week intervals) is essential to monitor the results and to prevent regrowth between too-widely-spaced treatment intervals. The benefit of treating subclinical HPV infection in the absence of cervical dysplasia is unclear. Examination and treatment of sex partners is of uncertain benefit.

Because HPV infection is so prevalent, and because it is uncertain whether treatment reduces infectivity, current approaches to the prevention and eradication of HPV infection focus on HPV vaccines. There are now 3 HPV vaccines licensed for use in the United States for the prevention of cervical cancer: the quadrivalent (HPV4) vaccine containing virus-like particles

prepared from the recombinant L1 capsid proteins from HPV types 6, 11, 16, and 18; the bivalent (HPV2) vaccine containing virus-like particles prepared from the recombinant L1 capsid proteins from HPV types 16 and 18; and a 9-valent vaccine that offers protection against HPV types 6, 11, 16, 18, 31, 33, 45, 52, and 58. ACIP recommends routine vaccination of females aged 11 or 12 years with 3 doses of HPV2, HPV4, or HPV9, but the vaccination series can be started beginning at age 9. The schedule for both vaccines is the same: the second dose should be administered 1 to 2 months after the first, and the third dose is administered 6 months after the first. The minimum intervals between doses are as follows: 4 weeks between the first and second doses, 12 weeks between the second and third doses, and 24 weeks between the first and third doses. Doses administered at time intervals shorter than what is recommended should be repeated. Vaccination with any of the 3 vaccines is also recommended for adolescent and young adult women ages 13 to 26 who have not been vaccinated previously or have not received all 3 doses. Women who turn 26 before completing the series can receive the additional doses. The Advisory Committee on Immunization Practices (ACIP) recommends the HPV2, HPV4 and HPV9 vaccines for the prevention of cervical cancer. The HPV4 and HPV9 vaccines are also recommended for the prevention of genital warts.

The US Food and Drug Administration also licensed the use of the HPV4 and HPV9 vaccines in males aged 9 to 26 years. Vaccination of males with HPV4 or HPV9 vaccine is recommended for males aged 13 to 21 years who have not previously been vaccinated or have not received all 3 doses; males aged 22 to 26 years may be vaccinated. HPV vaccination (HPV4 or HPV9) is recommended through age 26 years for men who have sex with men and for individuals with HIV or other immunocompromising conditions. Recent data demonstrate that the HPV4 vaccine prevents infection with HPV-6, 11, 16, and 18 and related external genital lesions in males 16 to 26 years old.

Finally, the US Food and Drug Administration approved the use of the HPV4 and HPV9 vaccines for prevention of anal cancers and associated precancerous lesions caused by the HPV types included in the HPV4/HPV9 vaccines in male and female adolescents and young adults 9 to 26 years old.

### Herpes Genitalis

Herpes simplex viral infections of the male and female genital tract are particularly distressing to patients because of the potential for recurrence after an initial episode, especially if caused by infection with herpes simplex virus (HSV) type 2. HSV-1 and HSV-2 can cause genital tract disease; in recent years, infection with HSV-1 has accounted for an increasing proportion of genital herpes infections. In a recent study at a university health center, just under 80% of culture-positive genital herpes infections among 18- to 24-year-olds were caused by HSV-1. Although genital herpes infections were once thought to be associated with the development of cervical cancer, current evidence indicates that HSV more likely acts as a cofactor. Sero-prevalence surveys indicate that the prevalence of

HSV-2 infection among adolescents aged 14 to 19 years decreased dramatically from the early to the late 1990s, with a smaller but still significant decline for HSV-1.

Infections with the virus can be classified as primary or nonprimary. Primary infection refers to infection with HSV-1 or HSV-2 in an individual without prior antibody to either virus. Nonprimary infection occurs in those with existing antibody to either HSV-1 or HSV-2 who become infected with the other strain. This type of infection, which almost always occurs in individuals who have existing antibody to HSV-1 who then become infected with HSV-2, tends to be less symptomatic. At least 10% of individuals (but probably many more) with a first symptomatic clinical episode of genital herpes have serologic evidence of previous HSV-2 infection.

In primary infection, symptoms usually occur within 2 to 20 days after sexual exposure. The patient experiences burning or itching at the site of inoculation, followed by erythema and the development of discrete vesicles. Initially, the vesicles contain clear fluid, but they rapidly form pustules with an erythematous base. Typically, a patient may have 15 to 30 vesicles, each full of infectious viral particles. Lesions are located on the vulva, cervix, clitoris, or perineum (see Figure 330-7). In male adolescents, they may occur on the penile shaft, glans, or prepuce (see Figure 330-8). Infection also can involve the urethra, leading to dysuria or urinary retention. Vesicles can be seen on the thighs, buttocks, groin, or perianal region as a result of autoinoculation or anal receptive intercourse. Because primary infection represents the first episode of infection with the particular virus type, systemic symptoms such as fever, malaise, and headache are common. Approximately 50% of patients have tender inguinal lymphadenopathy.

After 2 to 4 days, the pustules break open and coalesce to form wet ulcers. This event is usually when patients seek health care. New lesions still may be developing at this point (with a peak at 7–11 days), but within 20 days, all the lesions have crusted over, and the pain and other symptoms have disappeared. The lesions generally heal without scarring.

The diagnosis of herpes genitalis is made most often on clinical grounds. Cell culture and polymerase chain reaction (PCR) testing are the preferred tests for detection of HSV infection. The sensitivity of culture declines as lesions begin to heal and is low for recurrent lesions. PCR assays are more sensitive than culture, but a negative culture or PCR test does not exclude herpes infection. Because recurrence rates for genital HSV-1 and HSV-2 differ significantly, testing should be performed whenever a patient presents with new-onset genital herpes.

After the infection resolves, the virus remains latent in the sacral ganglia and may reactivate at any time. This reactivation is referred to as *recurrent disease*. Recurrences may occur in association with stress, local trauma, fever, or menstruation and tend to be shorter and less symptomatic. Vesicles usually occur near the initial infection site but tend to be fewer in number. Just before the recurrence, the patient may experience burning or itching at the site of infection. Healing takes place within 1 to 2 weeks.

Female adolescents whose only site of recurrence involves the cervix may be unaware of it, although

**Figure 330-7** Genital herpes of the vulva. (From Holmes K, et al, eds. Sexually Transmitted Diseases. 3rd ed. New York: McGraw-Hill; 1999. Reprinted by permission from McGraw-Hill Education.)

**Figure 330-8** In herpes genitalis, the blisters break, leaving tender ulcers that may take 2 to 4 weeks to heal the first time they occur. (Courtesy Red Book Online. [redbook.solutions.aap.org](http://redbook.solutions.aap.org))

they are shedding the virus. Approximately one-third of male adolescents also may have unapparent recurrences but are still infectious. Asymptomatic reactivation is most likely to happen within 6 months after the initial infection. Hence, unless sex partners reveal their history of infection, many exposures can occur without an individual being aware that contact with the virus has been made. Many HSV-seropositive patients who deny a history of genital herpes actually have lesions that they fail to recognize as herpes. Nevertheless, they are capable of infecting their sex partners. A recent study demonstrated that asymptomatic genital shedding of HSV-2 occurred on 26% of days in the first year following the initial episode, on 13% of days in years 1 to 9, and on 9% of days after 10 or more years had elapsed.

In the year after a first documented episode of genital HSV-2 infection, 90% of individuals will

have at least 1 recurrence; approximately one-third will have 6 or more, and one-fifth will have 10 or more. The risk of recurrence depends on many factors. Male adolescents are somewhat more likely to have recurrent disease, as are those whose infection was caused by HSV-2. Once a second episode occurs, the patient is likely to have multiple recurrences.

Development of antiviral drugs such as acyclovir, famciclovir, and valacyclovir has dramatically altered the nature of herpes therapy. These agents greatly reduce the symptoms associated with primary episodes of genital herpes and decrease the duration of virus shedding and the time to resolution of lesions (see Box 330-4). Some patients with recurrent disease may derive benefit from therapy if the medication can be initiated during the prodrome or within 1 day after onset of lesions. Those who have 6 or more recurrences per year have a 75% reduction in recurrences with daily suppressive therapy (see Box 330-4). Patient-initiated administration of a single-day course of famciclovir also shortens the duration of recurrences. Valacyclovir reduces asymptomatic virus shedding and reduces the risk of infection in couples serodiscordant for HSV-2. A successful HSV vaccine has been elusive.

### Syphilis

Rates of primary and secondary syphilis decreased by 90% from 1990 to 2000, reaching a low of 2.1 cases per 100,000 people in 2000. Since then, rates have increased steadily (reaching 6.3 cases per 100,000 people in 2014). Among 15- to 24-year-olds, rates of infection increased between 2005 and 2009 among white, black, and Hispanic males and among white and black females. Since 2000, the largest increase has been among men who have sex with men. Syphilis remains a significant problem in the South and in some urban areas.

The typical chancre of syphilis develops at the site of intimate sexual contact approximately 2 to 3 weeks after exposure to an infected individual. This lesion, which varies in size from a few millimeters to a few centimeters, is painless, has a clean base, and has sharply demarcated, indurated borders. Multiple ulcers may be present. Lymphadenopathy is usually present, often bilaterally. Because the ulcer is painless, its appearance in the vagina or rectum or even in the mouth is likely to go unnoticed. While the ulcer is present, the exudate overlying it is highly infectious. Untreated, the chancre disappears in 3 to 6 weeks.

The rash of secondary syphilis appears 4 to 10 weeks after the chancre appears in the untreated patient. Hence, the rash and the chancre may coexist. Because the spirochetes spread hematogenously from the site of initial infection, constitutional symptoms such as fever, malaise, sore throat, and generalized lymphadenopathy may be present.

The rash is typically papulosquamous but can be macular or pustular. Initially, it involves the trunk and flexor surfaces of the arms but then spreads to the entire body, including the palms, soles, and mucous membranes (see Figure 330-9). Physicians should

**Figure 330-9** A 16-year-old girl with the rash of secondary syphilis. The signs and symptoms of secondary syphilis generally occur 6 to 8 weeks after the primary infection, when primary lesions are healed. (Courtesy Red Book Online. [redbook.solutions.aap.org](http://redbook.solutions.aap.org))

strongly consider screening any sexually active adolescent with a generalized eruption (eg, that seen with pityriasis rosea) for syphilis. Annular papules can appear on the face, and the rash can resemble impetigo or eczema. In some cases, moist, fissured papules or raised, thickened papules (condyloma lata) are seen; both are highly infectious. Finally, loss of scalp or eyebrow hair can be associated with secondary syphilis. The rash disappears spontaneously 3 to 12 weeks after its appearance; at this point, the patient is classified as having latent syphilis.

At the time the chancre is present, a dark-field examination of the nonbloody exudate should be performed by an expert in dark-field microscopy. If performed on 3 successive days, the likelihood of obtaining a positive result from an infected individual is extremely high. If the results of all 3 examinations are negative, then the diagnosis of primary syphilis should be reconsidered. If the dark-field examination is unavailable, then a serologic test for syphilis should be performed. Currently, there are 2 types of serologic tests for syphilis: nontreponemal (Venereal Disease Research Laboratory [VDRL] and RPR) and treponemal (eg, fluorescent treponemal antibody absorbed [FTA-ABS]); some laboratories are now performing initial screening of samples using a treponemal test rather than the traditional method of performing the nontreponemal test first. Using only 1 type of test is insufficient for making the diagnosis, because both tests have limitations. For example, false-positive nontreponemal test results may be obtained in individuals with autoimmune disorders. However, because all the symptoms of syphilis may not be consistently present in everyone infected, most adolescents infected with syphilis will be identified only through routine serologic screening; therefore, testing at-risk youth is important.

Criteria for determining the stage of infection (primary versus secondary syphilis), recommended CDC treatment guidelines for each stage, and guidelines for appropriate follow-up testing are outlined in Box 330-4. All patients with syphilis should be screened for HIV infection.

### ***Mycoplasma genitalium* and *Ureaplasma urealyticum***

The role of *Mycoplasma genitalium* and *Ureaplasma* species in causing disease continues to evolve. *M. genitalium* causes 15% to 20% of nongonococcal urethritis (NGU), 20% to 25% of nonchlamydial NGU, and approximately 30% of persistent or recurrent urethritis. In most settings, infection with *M. genitalium* is more common than with *N. gonorrhoeae* but less common than with *C. trachomatis*. Its role in female reproductive tract disease is less clear. *M. genitalium* can be found in the vagina, cervix, and endometrium, and infections in women are commonly asymptomatic. The organism can be found in 10% to 30% of women with clinical cervicitis, and most studies have found that it is more common in women with cervicitis compared to those without. *M. genitalium* is found in the cervix and/or endometrium of women with PID more often than in women without. It has been detected in 2% to 22% of PID cases, but the frequency with which *M. genitalium*-infected women develop PID is unclear. Overall, evidence suggests that *M. genitalium* can cause PID but this occurs less often than with *C. trachomatis*. The 7-day doxycycline treatment regimen for urethritis is largely ineffective to treat *M. genitalium*. One gram by mouth of azithromycin is effective, but resistance is rapidly emerging. A longer course of azithromycin (500 mg on day 1 followed by 250 mg daily for 4 days) may be marginally more effective, but people who failed the 1 g course generally do not respond to a longer course. Moxifloxacin (400 mg daily for 7, 10, or 14 days) has been successfully used to treat men and women with previous treatment failures, but the drug has not been tested in clinical trials.

*Ureaplasma* species have now been differentiated into *U. urealyticum* (UU) and *U. parvum* (UP). Recent studies suggest that UU (but not UP) causes urethritis, which may explain why previous studies examining the role of *Ureaplasma* species as a cause of urethritis have been conflicting.

## **SYNDROMES ASSOCIATED WITH SEXUALLY TRANSMITTED INFECTIONS**

### **Pelvic Inflammatory Disease**

Pelvic inflammatory disease refers to infection involving the upper genital tract (uterus, fallopian tubes, ovaries, and pelvis) of women; it often occurs as a result of undetected or inadequately treated STIs of the lower genital tract (endocervix). In the short term, PID can lead to such problems as a tubo-ovarian abscess. In the long run, infertility, chronic pelvic pain, and increased risk for ectopic pregnancy are attributable to this condition, even when the acute episode has been managed appropriately. Among all sexually active girls and women, teenagers younger than 19 years are at greatest risk for contracting this disease; the risk is 1:8 for sexually active 15-year-olds and 1:16 for 16-year-olds, but only 1:80 for 24-year-olds. Because a major risk factor for developing PID is a prior episode, adolescent girls who experience this illness early in their reproductive life cycle are at great risk for having further significant problems.

Even though the condition is common, the diagnosis of PID is imprecise. Studies have shown that clinical diagnosis of PID has a positive predictive value for salpingitis of 65% to 90%, with the positive predictive value being higher for adolescents and in clinical settings in which the prevalence of STIs such as chlamydia or gonorrhea is high. Signs and symptoms can be nonspecific, and the only sure method for diagnosis, laparoscopy, is not routinely performed for diagnostic purposes in the United States. Physicians must therefore maintain a high index of suspicion, obtain an extensive history, and perform a thorough physical examination to avoid a misdiagnosis.

When eliciting a history from a patient who has lower abdominal pain, the physician should keep in mind specific factors that place an individual at risk for infection. Failure to use barrier methods of contraception, douching, the presence of a newly inserted intrauterine device, multiple partners, a recent change in partner, or history of other STIs or PID should raise concern. The presence of a new vaginal discharge (or a change in odor, color, or amount), abnormal menstrual bleeding (increased or prolonged; occurring at the wrong time in the cycle), or dyspareunia are all suggestive of PID. Other symptoms include dysuria, dysmenorrhea (usually more severe than normal), nausea, vomiting, diarrhea, fever, and malaise. Except for dysmenorrhea, these symptoms also can be seen in patients who have diseases of the urinary tract (eg, pyelonephritis) or gastrointestinal tract (eg, appendicitis).

Depending on the extent of upper genital tract involvement, physical signs may include pain on movement of the cervix and endometrial or adnexal tenderness, or both. Fever is present in less than 50% of patients who have documented PID. If the infection has spread to involve the capsule of the liver, right upper quadrant tenderness also may be elicited. With extensive infection, signs of peritonitis, particularly rebound tenderness, are present. The palpation of an adnexal mass raises the concern of a coexisting tubo-ovarian abscess. Mucopus visible in the cervical os strongly suggests the presence of infection, but its absence does not rule out the diagnosis. Acute-phase reactants lack the necessary sensitivity and specificity to be helpful in establishing the diagnosis of PID. Although 60% to 80% of patients have an increased WBC count, sedimentation rate, or C-reactive protein, so do 20% to 50% of patients with abdominal pain who do not have PID. Estimates suggest that up to 60% of cases of PID are subclinical.

The CDC's 2015 sexually transmitted disease treatment guidelines recommend that treatment of PID be initiated in sexually active young women if "they are experiencing pelvic or lower abdominal pain, if no cause for the illness other than PID can be identified, and if 1 or more of the following minimum criteria are present on pelvic examination: cervical motion tenderness OR uterine tenderness OR adnexal tenderness." Other supportive criteria for PID are listed in Box 330-5. The physician should take particular note that certain surgical emergency conditions can mimic PID. Hence, the differential diagnosis, as outlined in Box 330-6, should be kept in mind. Because many teenagers at risk for PID are similarly at risk for pregnancy, and

because ectopic pregnancy can mimic PID, a urine or serum pregnancy test should be routinely obtained at the time of evaluation. If an adnexal mass is palpated or suspected, then an ultrasound should be obtained to determine whether a tubo-ovarian abscess is present. Testing for *C trachomatis* and *N gonorrhoeae* should occur routinely.

Treatment is directed toward eradicating the organism responsible for the infection. Unfortunately, the exact nature of the infection is established with great difficulty. Test results obtained from cervical specimens do not necessarily reflect the nature of the endometrial or tubal infection. Many organisms thought to play a role in PID are difficult to grow in culture; thus, studies that do not use state-of-the-art culture techniques may not identify all relevant organisms. Studies that have been performed emphasize the polymicrobial nature of the infection. *N gonorrhoeae*, *C trachomatis*, or both are recovered from approximately 25% to 75% of adolescents and young adults with PID. Facultative and anaerobic bacteria, as well as organisms associated with bacterial vaginosis, have been recovered from various points in the upper genital tract of women who have PID.

As a result of the uncertainty concerning the nature of the infecting organisms, the CDC treatment regimens outlined in Box 330-4 reflect empirical therapy based on the assumption that the infection is polymicrobial. If outpatient therapy is to be attempted, careful follow-up at 48 hours must be ensured, and a mechanism for hospitalizing the patient before that time if symptoms worsen must be in place.

Once therapy is initiated, the patient should improve within 48 to 72 hours. Failure to see improvement should raise concerns about the accuracy of the diagnosis or the presence of complications; reassessment of the initial antimicrobial regimen should also occur. Additional diagnostic testing (eg, diagnostic laparoscopy) should also be considered. Approximately 10% to 20% of patients who have PID develop a tubo-ovarian abscess; 3% to 15% of these abscesses rupture. Depending on the experience of the physician, consultation with a gynecologist should be considered if an abscess is detected or if the patient fails to improve. Consultation with a surgeon is recommended if concern exists that the patient has appendicitis.

If hospitalized (see Box 330-7), the patient may be switched to oral therapy 24 to 48 hours after she demonstrates substantial clinical improvement. Treatment must include a total of 14 days of therapy with doxycycline (or other suitable oral regimens), and follow-up at completion of treatment is essential. The patient should be instructed not to have intercourse until her therapy is completed and her partner is notified and treated. Because an episode of PID is a major risk factor for development of a second episode, the use of barrier methods of contraception must be stressed to the patient.

Even with optimal diagnosis and treatment, the long-term morbidity from a single episode of PID can be significant. Long-term complications include tubal factor infertility, increased risk for ectopic pregnancy, and chronic pelvic pain.

**BOX 330-5 Diagnostic Considerations of Pelvic Inflammatory Disease**

Acute pelvic inflammatory disease (PID) is difficult to diagnose because of the wide variation in the symptoms and signs. Many women with PID have subtle or mild symptoms that do not readily indicate PID. Consequently, delay in diagnosis and effective treatment probably contributes to inflammatory sequelae in the upper reproductive tract. Laparoscopy can be performed to obtain a more accurate diagnosis of salpingitis and a more complete bacteriologic diagnosis. However, in many instances, this diagnostic tool is not readily available for acute cases, and its use is not easy to justify when symptoms are mild or vague. Moreover, laparoscopy will not detect endometritis and may not detect subtle inflammation of the fallopian tubes. Consequently, a diagnosis of PID is usually based on clinical findings.

The clinical diagnosis of acute PID is imprecise. Data indicate that a clinical diagnosis of symptomatic PID has a positive predictive value of 65% to 90% for salpingitis in comparison with laparoscopy. The positive predictive value of a clinical diagnosis of acute PID differs depending on epidemiologic characteristics and the clinical setting, with higher positive predictive value among sexually active young (especially adolescent) women, among patients attending sexually transmitted disease clinics, or in settings in which rates of gonorrhea or chlamydia are high. In all settings, however, no single historical, physical, or laboratory finding is both sensitive and specific for the diagnosis of acute PID (ie, can be used both to detect all cases of PID and to exclude all women without PID). Combinations of diagnostic findings that improve either sensitivity or specificity do so only at the expense of the other. For example, requiring 2 or more findings excludes more women who do not have PID but also reduces the number of women with PID who are identified.

Many episodes of PID go unrecognized. Although some cases are asymptomatic, others are undiagnosed because the patient or the primary care physician fails to recognize the implications of mild or nonspecific symptoms or signs (eg, abnormal bleeding, dyspareunia,

vaginal discharge). Because of the difficulty of diagnosis and the potential for damage to the reproductive health of women, even by apparently mild or subclinical PID, primary care physicians should maintain a low threshold for the diagnosis of PID. The optimal treatment regimen and long-term outcome for women with asymptomatic or subclinical PID are unknown. The following suggestions for diagnosing PID are intended to help primary care physicians recognize when PID should be suspected and when they need to obtain additional information to increase diagnostic certainty. These suggestions are based partially on the fact that diagnosis and management of other common causes of lower abdominal pain (eg, ectopic pregnancy, acute appendicitis, functional pain) are unlikely to be impaired by initiating empiric antimicrobial therapy for PID.

Empiric treatment of PID should be initiated in sexually active young women and others at risk for sexually transmitted diseases if they are experiencing pelvic or lower abdominal pain, if no other cause for the illness other than PID can be identified, and if 1 or more of the following minimal criteria are present on pelvic examination: cervical motion tenderness or uterine tenderness or adnexal tenderness. Requiring that all 3 of the minimal criteria listed previously be present before initiating antibiotic treatment might result in insufficient sensitivity for diagnosing PID.

More elaborate diagnostic evaluation is often needed, because incorrect diagnosis and management might cause unnecessary morbidity. Additional criteria that can be used to enhance the specificity of the minimal criteria and support a diagnosis of PID include the following:

- Oral temperature above 101°F (38.3°C)
- Abnormal cervical or vaginal mucopurulent discharge
- Presence of abundant numbers of white blood cells on saline microscopy of vaginal secretions
- Increased erythrocyte sedimentation rate
- Increased levels of C-reactive protein
- Laboratory documentation of cervical infection with *N gonorrhoeae* or *C trachomatis*

Adapted from Workowski KA, Bolan GA. Sexually transmitted diseases treatment guidelines 2015. *MMWR Recomm Rep*. 2015;64 (RR-64): 1-134. (In some cases, the author has edited the text to condense it.)

**Perihepatitis (Fitz-Hugh–Curtis Syndrome)**

Perihepatitis associated with gonococcal salpingitis was described in 1920. Subsequently, Fitz-Hugh described a patient who had *violin string* adhesions between the liver and anterior abdominal wall, and Curtis described localized peritonitis of the liver's anterior surface in a woman who had upper abdominal pain and tenderness who was undergoing laparotomy for suspected gallbladder disease. Since then, the fact that *C trachomatis* infections can cause a similar picture has been well documented.

Onset of upper abdominal pain usually follows (but can also precede) the onset of lower abdominal pain. The pain generally occurs on the patient's right side and can radiate to the shoulder. Less than 50% of

patients have mildly increased liver enzyme levels. Treatment for PID also eliminates the perihepatitis.

**Epididymitis**

Epididymitis is characterized by the acute or subacute onset of unilateral scrotal pain; adolescent boys may complain of testicular pain. Preceding symptoms include urethral discharge and dysuria, but these symptoms may be so mild that they are easily ignored. Fever may be present. At physical examination, tenderness may occur on palpation of the epididymis, but the testicle may also be slightly tender. A hydrocele may be present, and the spermatic cord may also be swollen and tender. Urethral discharge may or may not be present at the time of diagnosis.

### BOX 330-6 Differential Diagnosis of Acute Lower Abdominal Pain in Adolescent Girls by Organ System

- Tubo-ovarian abscess

From Shafer M, Sweet RL. Pelvic inflammatory disease in adolescent females. *Pediatr Clin North Am*. 1989;36:513–532. Copyright © 1989, Elsevier, with permission.

Supportive laboratory evidence for the diagnosis of epididymitis includes (1) a positive leukocyte esterase test on a first-catch urine specimen (the first 20 mL of urine voided) or the presence of more than 10 WBCs per high-power field if the first-catch urine specimen is spun down and the sediment examined, or (2) Gram stain of urethral secretions showing more than 5 WBCs per oil-immersion field. If the Gram stain also shows WBCs containing intracellular gram-negative diplococci, *N gonorrhoeae* should be considered the causative agent.

In adolescents, the physician must rule out testicular torsion. Depending on the presentation and laboratory evidence, additional studies (nuclear scan or Doppler flow study) or consultation with a urologist may be necessary.

Among sexually active adolescents, acute epididymitis is most frequently caused by *N gonorrhoeae* or *C trachomatis*. Sexually transmitted enteric organisms (eg, *Escherichia coli* and *Pseudomonas* spp) may be the causative agent in male adolescents who are the insertive partner during anal sex. Patients with epididymitis should be tested for *N gonorrhoeae* and *C trachomatis*.

Most patients can be managed on an outpatient basis. Hospitalization should be considered if the pain is particularly severe (suggesting an alternate diagnosis such as torsion, testicular infarction, or abscess), when patients are febrile, or if noncompliance is of concern.

### BOX 330-7 Suggested Indications for Hospitalization of Patients With Pelvic Inflammatory Disease (PID)

In women with PID of mild or moderate clinical severity, outpatient therapy yields short- and long-term clinical outcomes similar to inpatient therapy. The decision of whether hospitalization is necessary should be based on the judgment of the primary care physician and whether the patient meets any of the following suggested criteria:

- Surgical emergencies such as appendicitis cannot be excluded
- The patient is pregnant
- The patient does not respond clinically to oral antimicrobial therapy
- The patient is unable to follow or tolerate an outpatient oral regimen
- The patient has severe illness, nausea and vomiting, or high fever
- The patient has a tubo-ovarian abscess

No evidence is available to suggest that adolescents benefit from hospitalization for treatment of PID. The decision to hospitalize adolescents with acute PID should be based on the same criteria used for older women. Younger women with mild to moderate PID have similar outcomes with either outpatient or inpatient therapy, and clinical response to outpatient therapy is similar among adolescents and older women.

At least 24 hours of direct inpatient observation is recommended for patients who have tubo-ovarian abscesses.

From Workowski KA, Bolan GA. Sexually transmitted diseases treatment guidelines 2015. *MMWR Recomm Rep*. 2015;64 (RR-64): 1–134. (Most of the information contained herein is reproduced verbatim from the Treatment Guidelines. In some cases, the author has edited the text to condense it.)

Treatment of epididymitis is outlined in Box 330-4. Adolescents treated as outpatients should be followed up within 48 to 72 hours of initiating treatment. Failure to improve should prompt re-evaluation of the diagnosis and the treatment. The sex partners of adolescents with epididymitis suspected of being or confirmed to be caused by chlamydia or gonorrhea should be evaluated and treated if their contact with the index patient occurred fewer than 60 days before the onset of the patient's symptoms.

#### Enteric Infections

The syndromes of proctitis and proctocolitis are limited mostly to adolescent boys who practice anal receptive intercourse. Symptoms include anorectal pain, tenesmus, constipation, and anal discharge. Those who have proctocolitis or enteritis will have diarrhea. Patients who have proctitis (the distal 10–12 cm of the rectum) should be examined with anoscopy and evaluated for *C trachomatis* (including LGV serovars), *N gonorrhoeae*, herpes simplex, and *T pallidum* infection. Treatment should be with standard doses of ceftriaxone and doxycycline (see Box 330-4).

Patients who have symptoms suggesting proctocolitis (the symptoms of proctitis plus diarrhea or abdominal cramps) should receive more extensive evaluation. Organisms such as *E histolytica*, *Campylobacter* species, the LGV serovars of *C trachomatis*, and *Shigella* species can be sexually transmitted. HIV-infected patients may be infected with opportunistic organisms such as CMV.

Enteritis usually occurs among patients whose sexual behaviors include oral-anal contact. Symptoms are usually limited to abdominal pain and diarrhea; the other symptoms of proctitis and proctocolitis are absent. Among immunocompetent patients, *G lamblia* is the most likely organism; a variety of organisms can cause enteritis in HIV-infected patients.

### Vaginitis

As discussed in Chapter 205, Vaginal Discharge, *T vaginalis*, an important cause of vaginitis among sexually active adolescents, is a sexually transmitted infectious agent. Bacterial vaginosis, which is associated with the overgrowth of *G vaginalis*, displays some characteristics of an STI. Bacterial vaginosis is associated with having multiple sex partners, with having a new sex partner, and with douching. Male sex partners of women who have bacterial vaginosis are more likely to have *G vaginalis* recovered from the urethra than are controls. However, this same organism can be recovered from approximately 15% of women who have never been active sexually. Furthermore, treatment of male partners does not seem to influence recurrence risks for women who are treated for bacterial vaginosis.

Vaginitis in and of itself can be distressing enough. However, current concerns about bacterial vaginosis center on its possible role in the pathogenesis of PID. Nongonococcal, nonchlamydial pathogens associated with PID are recovered more often from the endometrium of women who have bacterial vaginosis than from those who do not. Bacterial vaginosis has been causally related to postpartum endometritis. Thus, treatment of symptomatic women who have bacterial vaginosis is warranted; asymptomatic women who are scheduled to undergo abortion or hysterectomy should also be treated.

### Cervicitis

Cervicitis is characterized by a purulent or mucopurulent discharge from the endocervical os or by significant endocervical bleeding (or both) that is induced when a swab is introduced into the os. It may be detected during a routine pelvic examination even if an adolescent has no genital complaints.

Both *C trachomatis* and *N gonorrhoeae* can cause cervicitis (an association that is stronger in women younger than 25 years), as can *Trichomonas* and HSV, especially HSV-2. *M genitalium*, bacterial vaginosis, and frequent douching may cause cervicitis. However, in most cases of cervicitis, no etiologic agent is identified.

Women with cervicitis should be carefully evaluated for PID and for the presence of trichomonas and bacterial vaginosis; they should also be tested for chlamydia and gonorrhea. Women with cervicitis who are 25 years or younger, who engage in unprotected sex, or who have a new sex partner, a sex partner with

concurrent partners, or a sex partner with an STI should be presumptively treated for *C trachomatis* and *N gonorrhoeae* (see Box 330-4), especially if follow-up is uncertain or if the physician does not have access to NAAT. Sex partners should be identified, evaluated, and treated, depending on the characteristics of the index patient. A follow-up visit should be scheduled to determine if the cervicitis has resolved. According to the 2015 CDC guidelines, “Women with persistent or recurrent cervicitis despite appropriate treatment should be evaluated for possible re-exposure or treatment failure.” Management options for persistent cervicitis are undefined and whether repeat or prolonged antibiotic regimens are effective is not known.

### Urethritis

All adolescent and young adult males with suspected or confirmed urethritis should be tested for gonorrhea and chlamydia and treated according to standard protocols (see Box 330-4). The etiology of urethritis in adolescents who test negative for gonorrhea and chlamydia with NAAT is unclear. *M genitalium* accounts for 15% to 25% of NGU in the United States. *T vaginalis*, HSV, and adenovirus can cause urethritis. NGU can be acquired through oral-penile contact; Epstein-Barr virus (EBV) can also cause urethritis. As discussed previously, the differentiation between *U urelalyticum* (which does seem to be capable of causing urethritis) and *U parvum* (which does not) may help to further clarify the etiology of nongonococcal, nonchlamydial urethritis.

The 2015 CDC guidelines state that adolescents with recurrent and persistent urethritis “should first be evaluated to make certain that they have completed a full treatment course and were not reinfected by an untreated or new sex partner.” Objective evidence of urethritis should be sought before antibiotic treatment is begun. Recent studies show that the most common cause of recurrent or persistent NGU is *M genitalium*. Men initially treated with doxycycline should be treated with 1 g of azithromycin. Those who fail a regimen of azithromycin should be treated with moxifloxacin 400 mg PO for 7 days. *T vaginalis* can cause urethritis. The 2015 CDC guidelines state that in areas where *T vaginalis* is prevalent, men who have sex with women should be treated with 2 g PO of either metronidazole or tinidazole in a single dose.

### Sexual Assault

Comprehensive assessment and management of victims of sexual assault (see also Chapter 371, Rape) should address concerns about possible exposure to STIs, including HIV; what specimens to collect and what diagnostic tests to perform should be individualized. Among female victims of sexual assault, infections with chlamydia, gonorrhea, and trichomonas are those most commonly identified; bacterial vaginosis is also commonly diagnosed. The initial examination of a sexual assault victim can include the following: NAATs for detection of *C trachomatis* and *N gonorrhoeae*; baseline testing for syphilis, hepatitis B, and HIV; and a vaginal wet prep to look for evidence of bacterial vaginosis and to obtain specimens for detection of trichomoniasis.

As follow-up with sexual assault victims is often suboptimal, preventive therapy for STIs should be encouraged. This includes empiric treatment for chlamydia, gonorrhea, and trichomonas (ceftriaxone 250 mg IM plus azithromycin 1 g PO in a single dose plus metronidazole 2 g PO in a single dose or tinidazole 2 g PO in a single dose); HPV vaccination for those who have not received any doses or have failed to complete the series; and hepatitis B vaccination with or without hepatitis B immunoglobulin depending on the vaccination status of the victim and the HBsAg status of the assailant, if known. Emergency contraception should also be offered.

Although the frequency is low, HIV seroconversion has occurred in individuals in whom the only identified risk factor was sexual assault. The nature of the assault, the infection status of the perpetrator, and genital lesions and STIs (clinically apparent or asymptomatic) in the victim all can influence the risk of transmission. If postexposure prophylaxis to prevent HIV infection is being considered, consultation with an HIV specialist is recommended.

Follow-up in 2 to 3 months is recommended to detect repeat or new infections and to monitor the serostatus of the victim if HIV or hepatitis B infection or syphilis is a concern.

### WHEN TO REFER

- If the physician is inexperienced in the diagnosis or management of: PID
  - Disseminated gonococcal arthritis
  - Syphilis (or positive VDRL, RPR or FTA-ABS test)
  - Anogenital warts
  - Genital herpes
  - Abnormal Pap smears
  - Recurrent or persistent urethritis
  - Proctitis, proctocolitis
- If postexposure prophylaxis for HIV infection is being considered in the management of a sexual assault victim
- In the case of sexual assault, survivors should be referred to a designated rape crisis center for evaluation and treatment if one is available

## Chapter 331 SINUSITIS

Tina Q. Tan, MD

Infection of the paranasal sinuses is common in children. Estimates indicate that 5% to 13% of viral upper respiratory tract infections in children are complicated by acute bacterial sinusitis. On average, children develop 5 to 10 upper respiratory tract infections yearly. The distinction between viral infections and acute bacterial sinusitis is based on the persistence and severity of upper respiratory symptoms.

### PATHOPHYSIOLOGY

The paranasal sinuses arise during fetal development as outpouchings beneath the turbinates in the nasopharynx. Only the maxillary and ethmoid sinuses are present at the time of birth. The sinuses continue to

develop and grow until adulthood (Table 331-1). The frontal sinuses develop last, appearing in most individuals after 10 years of age with continuing development through puberty. Growth may be asymmetrical, and some individuals lack one or more sinuses altogether. Various functions have been ascribed to the sinuses, but none of these have been proved. These functions include warming and humidifying inspired air, reducing the weight of the skull, providing thermal insulation to the central nervous system and sensory organs, affecting facial form, and serving as vocal resonators. Recent theories suggest that the sinuses serve as reservoirs for the production and absorption of antigens, allowing for the tolerance of infections until effective specific immunity develops.

The lining of the mucosa of the sinuses is similar to that of the nasopharynx, with pseudostratified, ciliated, columnar epithelium interspersed with goblet cells and submucosal glands. Cilia beat toward the ostium of the sinus to expel mucus and particulate matter into the nasopharynx. The ostia of the maxillary sinuses are located in the upper part of the chamber where cilia must battle gravity to clear secretions. This circumstance probably contributes to the high frequency of infection in these sinuses. Occlusion of the ostia, impairment of ciliary motility, and alterations in the consistency of mucus secretions alone or in combination can predispose the sinuses to infection.

Sinusitis occurs most often after a viral upper respiratory tract infection or as the result of nasal allergy. Inflammation and edema of the respiratory mucosa lead to obstruction of the ostium. Pressure changes in the sinus that result from occlusion or from blowing and sniffing through the nose allow bacteria to invade the normally sterile sinus cavity. Other disorders associated with sinusitis in children are listed in Box 331-1.

Respiratory viruses such as adenoviruses, influenza viruses, parainfluenza viruses, and rhinoviruses contribute to the development of sinusitis. The most common bacterial pathogens associated with acute sinusitis are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. *Staphylococcus aureus* and anaerobes are prevalent in chronic sinusitis, and *Streptococcus pyogenes* (group A *Streptococcus*) may be associated with both acute and chronic disease. Other organisms that may be found in patients with chronic sinusitis and those with altered immunity, particularly in those patients with cystic fibrosis, include gram-negative enteric organisms (eg, *Pseudomonas* species, *Escherichia coli*, *Proteus mirabilis*, *Klebsiella* species, and *Enterobacter* species), fungal pathogens, and anaerobes.

### CLINICAL PRESENTATION AND DIAGNOSIS

Sinusitis is primarily a clinical diagnosis, and differentiating upper respiratory tract infections or allergic rhinitis from acute sinusitis can be difficult in children. Most uncomplicated upper respiratory tract infections improve after 5 to 7 days. Symptoms that persist without improvement for more than 10 days suggest

**Table 331-1 Sinus Development**

SINUS	FIRST APPEARANCE	SIZE (mL)				AGE OF CLINICAL IMPORTANCE
		BIRTH	3 YEARS	10 YEARS	14 YEARS	
Maxillary	3 wk of fetal life	0.13	2.5	10.4	11.6	Birth
Ethmoid	6 mo of fetal life	0.06	0.16	2.4	4.8	Birth
Sphenoid	3 mo of fetal life	0.02	0.68	1.8	2.1	5 yr
Frontal	1 yr of life	—	0.08	1.0	3.6	10–12 yr

bacterial superinfection, and a diagnosis of acute sinusitis can be made. A similar history persisting for more than 30 days is consistent with both subacute or chronic sinusitis. Regardless of duration, cough, nasal discharge, and nasal congestion are the most common clinical manifestations of acute sinusitis. The cough occurs during the day and is often worse at night or when the child is supine. Nasal discharge may be clear or purulent. Parents of young children may report fetid breath. Headache and facial pain are manifestations of acute sinusitis that are uncommon in children. Painless swelling of the periorbital tissues without erythema, usually in the morning, is an occasional manifestation of sinusitis that may be confused with periorbital cellulitis in its early stage. The diagnosis of acute sinusitis may also be made in a patient with a significant worsening course of signs and symptoms

(worsening or new onset of nasal discharge, nasal congestion, daytime cough, or fever after initial improvement), often beginning on day 6 or 7 of illness after initial signs of improvement from an uncomplicated viral upper respiratory tract infection. A less common presentation of acute sinusitis is an unusually severe upper respiratory tract infection. In most cases of viral upper respiratory infection, fever precedes the onset of watery nasal discharge and is associated with constitutional symptoms. Thickening of nasal secretions occurs later in the course, before resolution. A high fever and purulent discharge that coexist for 3 or more days suggest the diagnosis of acute sinusitis.

On physical examination, the nasal mucosa is usually erythematous and swollen but may be pale and boggy. Mucopurulent material can sometimes be seen in the nose or draining into the nasopharynx. The presence of a foreign body in the nose must be ruled out. Palpation or percussion over the sinuses may elicit tenderness. Periorbital edema and mild discoloration of the skin below the eyelids is occasionally seen.

Routine use of radiographs to confirm the diagnosis of uncomplicated sinusitis is not recommended in young children, but may be useful in children older than 6 years of age when the diagnosis is in question or there is a poor response to treatment. In a patient with clinical signs and symptoms suggestive of acute sinusitis, bacteria are present in a sinus aspirate 75% of the time when maxillary sinus roentgenograms show air-fluid levels, complete opacification, or mucosal thickening of at least 4 to 5 mm. Cysts and polyps also may be seen on sinus roentgenograms.

Computed tomography (CT) imaging of the sinuses with pediatric windows should be reserved for patients who have frequent recurrences or persistent symptoms that are not improving, those who have complicated sinusitis accompanied by orbital or intracranial complications, and those for whom sinus surgery is being contemplated.

Transnasal aspiration of the maxillary sinuses can be performed by an otolaryngologist for diagnostic purposes in specific situations. Nasopharyngeal culture results correlate poorly with sinus culture results. Sinus aspiration and lavage are indicated only in children who fail to respond to conventional antibiotic therapy, in immunosuppressed patients, and in those whose illness is severe or life-threatening.

## COMPLICATIONS

Complications of sinusitis are most often caused by local extension of the disease. Orbital cellulitis is the most common serious complication of sinusitis. The ethmoid sinus is separated from the orbit by the thin lamina papyracea. Erosion of this bone leads to invasion of the orbit by bacterial pathogens. The eyelids appear intensely red and swollen on physical examination. Fever, malaise, and an increased white blood cell count are present. Orbital pain, proptosis, and limitation of eye movement (ophthalmoplegia) help distinguish this condition from preseptal (periorbital) cellulitis, although CT scanning may be needed to differentiate the 2 conditions. Treatment of orbital cellulitis involves parenteral antibiotics; an ophthalmologist and an otolaryngologist should be consulted to determine whether surgical drainage is indicated (see Chapter 319, Preseptal and Orbital Cellulitis). This complication has been reported most often in male adolescents who, in many cases, lack the common symptoms of sinusitis. However, more recent reports have shown a shift in the occurrence of orbital cellulitis toward a younger population, including infants. The reasons for this shift are unclear.

Intracranial infection, most commonly subdural empyema, is the second most common complication of sinusitis. Infection can occur by direct extension through necrotic bone or by bacterial spread through the venous system. The frontal sinuses are involved most often. These sinuses are the last to develop, appearing in most individuals by 10 years of age and continuing to develop during puberty; therefore, the peak age of incidence of this complication is between 10 and 20 years, although it can develop in younger children. Patients have a low-grade fever, malaise, and a frontal headache. Vomiting and a decreased level of consciousness appear as the disease progresses.

If a patient is thought to have an intracranial abscess, then a head CT scan with contrast should be obtained. Lumbar puncture should be avoided until intracranial mass effect has been ruled out. Treatment with high-dose parenteral antibiotics and neurosurgery to drain the abscess and to debride necrotic bone are required. Steroids and hypertonic agents, such as mannitol or glycerol, may be necessary to control intracranial hypertension.

Other, less common complications of sinusitis in children include meningitis, osteomyelitis of the frontal bone (*Pott's puffy tumor*), epidural abscess, and cavernous sinus thrombosis.

## TREATMENT

Treatment of sinusitis in children involves antibiotic therapy, symptomatic relief measures, and drainage, if necessary. Amoxicillin is an appropriate initial choice for treating uncomplicated sinusitis in geographic areas where the prevalence of  $\beta$ -lactamase-producing strains of *H influenzae* and *M catarrhalis* is low. In communities with a high prevalence of nonsusceptible *Streptococcus pneumoniae* (>10%, including intermediate- and high-level resistance attributable to altered penicillin-binding proteins), higher-dose amoxicillin

(80–90 mg/kg/day in 2 divided doses, with a maximum of 2 g per dose) should be considered. Macrolide antibiotics are an option for children allergic to amoxicillin or other  $\beta$ -lactam antibiotics. Broader coverage with amoxicillin plus clavulanate, a carbacephem, a third-generation cephalosporin, or a quinolone should be considered for children who fail to respond to amoxicillin. These alternatives also should be considered for the child who has been treated recently with amoxicillin, has frontal or sphenoid sinusitis, has complicated ethmoid sinusitis, or has very protracted symptoms. Clinical improvement should be expected within 48 hours, and a minimum of 10 days of antibiotic therapy usually is adequate. If symptoms fail to resolve completely within 10 days, then patients should be treated for an additional 7 days beyond the resolution of symptoms.

Decongestants, antihistamines, and saline nose drops have been recommended to help drain the sinuses, but no proof of the efficacy of these agents exists. Intranasal steroids may provide some benefit, particularly in the second week of therapy, but further research is necessary to clarify the value of such treatment.

In unusually severe cases, hospitalization and parenteral antibiotics may be required and otolaryngologic consultation is indicated. Some experts recommend antibiotic prophylaxis for the child who has recurrent sinusitis and no underlying disorder, although no scientific studies support this practice, and it may lead to the rapid development of antibiotic resistance. Surgery may be required in cases of medically recalcitrant severe chronic sinusitis in children.

## Recurrent Sinusitis

Children who have more than 2 to 3 episodes of acute bacterial sinusitis per year should receive evaluation for underlying conditions that can lead to this clinical pattern. The first step is a screening evaluation for allergic rhinitis. If this yields positive results, aggressive environmental controls and medication to reduce allergic inflammation (eg, montelukast, nasal antihistamines, or nasal steroids) should be instituted. If problems persist, the next step is to assess anatomy and to exclude a subtle presentation of chronic infection. A low-radiation limited sinus CT (eg, MiniCAT) can provide a quick, noninvasive, sensitive, and safe evaluation compared to rhinoscopy, plain radiographs, or traditional sinus CT. A positive study can help direct appropriate sinus lavage and define suboptimal sinus ostial anatomy. A poor clinical course despite assessment and treatment of allergic rhinitis and surgical intervention should raise concerns about a humoral immunodeficiency. This is particularly true if the child also has recurrent otitis media, bronchitis, and pneumonia.

Baseline screening evaluation includes quantitative immunoglobulins (IgG, IgA, IgM, IgE), CBC with differential, and CH50. Secondary tests include assessment of response to relevant specific antigens (eg, unconjugated pneumococcal vaccine). Such testing may uncover a child who would benefit from intravenous or subcutaneous gammaglobulin.

## Chapter 332 SPINA BIFIDA

Amy Houtrow, MD, PhD, MPH

## DEFINITION

Spina bifida is the most common type of neural tube defect. The term *spina bifida* refers to splitting of the vertebral arches. This split may be associated with protrusion of the meningeal sac, which may also include portions of the spinal cord or spinal nerves. When the split of the vertebral arches is isolated, the condition is called *spina bifida occulta*. Nearly one-fourth of the population has abnormalities of the posterior arches that are benign and without symptoms. When the meningeal sac protrudes between the split vertebral arches, the condition is called *meningocele*. When the meningeal sac also contains portions of the spinal cord or spinal nerves, the condition is called *myelomeningocele*. Frequently, physicians use the term *myelomeningocele* interchangeably with the term *spina bifida*. In this chapter, the term *spina bifida* will be used to describe the broad category of

conditions that includes the focus of this chapter: *myelomeningocele*.

## EPIDEMIOLOGY

Myelomeningocele is a complex congenital malformation with an incidence of 0.4 to 0.8 per 1,000 live births. The incidence of myelomeningocele and other neural tube defects is decreasing. Improved prepregnancy nutrition, including folic acid supplementation and fortification, and the establishment of prenatal diagnosis with elective termination have led to the decreasing incidence. The incidence is higher among girls, infants born in households with low socioeconomic status, and families of Hispanic, English, Irish, or Welsh descent. While the incidence is decreasing, the survivability is increasing because of improved medical and surgical care.

## ETIOLOGY AND RISK FACTORS

The etiology of myelomeningocele is unclear. The primary mechanism seems to be the faulty closure of the neural groove in the first 28 days of gestation. By this point in gestation, the neural tube that eventually becomes the spinal cord and vertebral arches is formed. Incomplete closure of the neural tube leads to myelomeningocele or other types of neural tube defects. This primary defect is often associated with the postembryonic development of hindbrain herniation (Chiari II malformation) and hydrocephalus, which can progress during fetal and postfetal development. The proposed mechanism of action is that a decrease in fourth ventricular pressure from cerebral spinal fluid leakage at the myelomeningocele site leads to limited expansion of the posterior fossa, which remains low; then as the hindbrain develops, the posterior fossa cannot accommodate this growth, leading to herniation. The subsequent lack of cerebral spinal fluid flow leads to hydrocephalus. The Chiari II malformation is present in a vast majority of individuals with myelomeningocele, and hydrocephalus is noted in most.

Both genetic and environmental factors influence neural tube closure. For example, abnormalities of the 5,10-methylene tetrahydrofolate reductase enzyme, which is involved in the metabolism of folic acid, predisposes individuals to spina bifida. There are other candidate genes being studied, but in total, the candidate genes only account for a small percentage of spina bifida cases. The current etiologic hypothesis is that spina bifida is the result of an interaction of multiple genes that are modifiable by environmental factors. This explains why only a small percentage of families who have a child with spina bifida have another affected child. However, an affected individual, their siblings, and their parents all have an increased risk for having a baby with spina bifida. The estimated recurrence risk for parents who have a child with spina bifida is 6.3%. Other risk factors include maternal exposure to hyperthermia, ethanol, valproic acid, carbamazepine, and isotretinoin. In addition, mothers with diabetes, obesity, or malnutrition have an increased risk for having a baby with neural tube defects. Myelomeningocele is also sometimes associated with other midline congenital defects and

chromosomal aberrations such as cri du chat syndrome and trisomy 13 and 18.

## DIAGNOSIS

Prenatally, the diagnosis of myelomeningocele is suspected when the  $\alpha$ -fetoprotein (AFP) level is high on prenatal triple or quadruple screening. AFP is found in the fetal spinal cord, spinal fluid, and brain. In the presence of an open neural tube defect, the AFP is detectable in the maternal circulation. If the maternal AFP level is high, an ultrasound should be conducted to identify specific abnormalities of the fetal head and spinal column. Cranial findings include a concave shape of the frontal calvarium (the lemon sign) and the posterior convexity of the cerebellum (the banana sign). Some centers also recommend amniocentesis to measure acetylcholinesterase. Mothers may elect not to pursue amniocentesis because of the potential risk for miscarriage. Other centers are also conducting fetal magnetic resonance imaging (MRI) to further delineate the abnormal anatomic findings. The diagnosis of myelomeningocele is formalized after birth. Inspection of the back should be conducted to determine the size and location of the open neural placode defect. Imaging studies of the head and spine should also be conducted. Serial head ultrasounds can be used to monitor the progression of hydrocephalus. A brain and spine MRI can identify the presence and severity of the Chiari II malformation as well as bony and spinal cord abnormalities (Figure 332-1). Neurologic (including an assessment of rectal tone and the anal wink) and orthopedic examinations should be conducted to assess for the functional and anatomic levels as well as spinal and limb deformities. Hip subluxation can be assessed using hip ultrasound, and a plain radiograph can identify spinal deformities such as hemivertebrae, kyphosis, and scoliosis.

Because there are many types of spina bifida and the consequences are variable, it is important to make the correct diagnosis and classification. An infant born with an open lesion or one covered by a thin membrane has either myelomeningocele or meningocele (no nervous tissue in the sac). A child born with a tuft of hair, hemangioma, red birthmark, sinus tract or dimple, or lipoma should be evaluated for occult spinal dysraphism. Children with occult spinal dysraphism are at increased risk for tethered spinal cord, fatty filum, infections, and neurologic deterioration. Infants with spinal dysraphism, meningocele, or myelomeningocele may have additional spinal cord abnormalities such as a split cord (diastematomyelia), a duplicated cord (diplomylia), a flattened malformed cord (myeloschisis), or a hypoplastic cord. MRI will confirm the diagnosis. Some infants with myelomeningocele also have caudal regression (sometimes referred to as sacral agenesis), a syndrome in which the lower portion of the body is underdeveloped. Infants and children with myelomeningocele should be classified based on anatomic level (where the lesion occurred) and motor level (what muscles are innervated well enough to perform muscle contraction for activities).

**Figure 332-1** Cranial magnetic resonance imaging showing abnormalities commonly found in myelomeningocele. (From Liptak GS, Dosa NP. Myelomeningocele. *Pediatr Rev.* 2010;31:443–450.)

## PATHOLOGIC CONSIDERATIONS IN MYELOMENINGOCELE

Four major malformations account for the findings associated with myelomeningocele: soft tissue malformations, vertebral body malformations, spinal cord malformations, and brain malformations. Table 332-1 lists these findings. The percentages of children with myelomeningocele with these findings is unknown (except when noted on the chart) because large epidemiologic studies have not been carried out.

### Soft Tissue Malformations

In myelomeningocele, the soft tissues of the back fail to close, which leaves the spinal cord open to infection and damage. In addition, lipomas or fatty tissue around the distal spinal cord may be present or develop. These may compress or restrict the movement of the spinal cord. Infants born with large soft tissue defects may require rotational muscle flaps and tissue expansions. In these cases, plastic surgeons are often involved in assisting neurosurgeons when performing primary closure of the back after birth.

### Vertebral Malformations

In addition to split vertebral arches, children with myelomeningocele may have absent, partial, fused, or butterfly vertebrae. Infants may be born with kyphotic, lordotic, or scoliotic deformities or may develop them later in life. The higher the spina bifida lesion, the more likely the child is to have kyphosis or scoliosis. Even in the absence of other vertebral abnormalities, children with myelomeningocele can develop neuromuscular scoliosis. Nearly 90% of children with lesions above the sacral level have kyphosis, scoliosis, or both. The consequences of scoliosis or kyphosis can be severe and include pulmonary and cardiac restriction, pain, skin breakdown, and spinal cord damage.

### Spinal Cord Malformations

The effects of myelomeningocele on the spinal cord can be quite extensive. Damage to the spinal cord can

**Table 332-1** Malformations Associated With Myelomeningocele

SOFT TISSUE	VERTEBRAL	SPINAL CORD	BRAIN
Lipoma	Split vertebral arches <sup>a</sup>	Split cord (diastematomyelia)	Chiari II malformation <sup>b</sup> : caudal displacement of the cerebellar tonsils, pons, and medulla (may also include brainstem kinking, aqueductal stenosis or forking, or beaking of the tectum)

<sup>a</sup>Split vertebral arches are necessary for diagnosis.<sup>b</sup>Chiari II malformation is almost always present.<sup>c</sup>Hydrocephalus is identified in 80% to 90% of cases.

lead to motor and sensory dysfunction. The loss of sensation can occur after predicted dermatomal patterns seen in spinal cord injury, but frequently individuals with myelomeningocele report spotty sensation that does not necessarily correspond to their motor or anatomic level. The loss of sensation puts the individual with myelomeningocele at risk for skin breakdown, burns, abrasions, and limited awareness of occult fractures. The loss of motor function from damage to the spinal cord or spinal nerves can lead to decreased movement in utero, which is associated with deformities seen at birth such as clubfeet and dislocated hips.

Motor function in infancy and childhood affects the child's attainment of developmental milestones. Most obvious is the delay or limited attainment of gross motor skills, but limitations in mobility in infancy have also been associated with poor development of visual perceptual skills. Ambulation is clearly affected by motor level, but other factors, including motivation, medical management, cognition, age, and obesity, also affect mobility. A major predictor of community and household ambulation is quadriceps strength. Although there are no hard and fast rules, having a sacral-level lesion is predictive of community ambulation, whereas children with lower lumbar lesions often successfully ambulate in the community but are more likely to use a wheelchair part-time. Children with high lumbar lesions tend to use a wheelchair primarily but may do some household or short-distance ambulation. Children with thoracic lesions tend to exclusively use wheelchairs for mobility. Therapeutic and bracing interventions can improve ambulation for most children with myelomeningocele.

Because the spinal cord and nerves supply the innervation to the intestines, the urinary system, and the reproductive system, virtually all individuals with myelomeningocele experience dysfunction in these areas. Individuals with myelomeningocele tend to have neurogenic bowel characterized by constipation and fecal incontinence. Constipation is the result of slow transit and delayed or incomplete expulsion of stool. Hindgut control by the enteric nervous system is modulated by

central connections from the sympathetic and parasympathetic nerves. In lower motor neuron bowel dysfunction, there is no spinal cord-mediated reflex peristalsis, which leads to a "relaxed" colon with slow propulsion. Incontinence is common because the external anal sphincter is denervated. In upper motor neuron bowel dysfunction, individuals experience constipation with fecal retention because their anal sphincter is spastic. Most children with myelomeningocele have lower motor neuron bowel dysfunction.

In addition to neurogenic bowel, nearly all children with myelomeningocele have neurogenic bladder, also referred to as neurogenic voiding dysfunction. The bladder has 2 main functions: storing urine produced by the kidneys and emptying the urine after the bladder is full. Bladder dysfunction is classified as either a failure to store urine or a failure to empty it. Storage failure is caused by a hypotonic bladder outlet or a spastic bladder. Emptying failure is caused by a spastic outlet or a hypotonic bladder. There can also be discoordination between bladder wall and bladder neck activities. The combination of a spastic bladder and a spastic outlet, which represents a dyssynergy between bladder contraction and relaxation of the external urinary sphincter, is a serious concern because of the likelihood of reflux and hydronephrosis, which can lead to permanent kidney damage.

Sexual functioning is neurologically complex, involving the autonomic and somatic nervous systems, and is frequently impaired in both men and women with myelomeningocele. Erectile dysfunction is common, and among those who can achieve erection, many have impaired ejaculation and decreased fertility. One study found that only 35% of men with myelomeningocele reported successful sexual intercourse. Women also experience difficulty with sexual functioning related to decreased sensation and lubrication, but they tend to have normal fertility. Many women with myelomeningocele can achieve orgasm.

### Brain Malformations

The most common brain malformation in myelomeningocele is the Chiari II malformation, in which the

brainstem and part of the cerebellum are displaced downward. Most have this malformation, although many children do not have symptoms associated with it. The symptoms, if present, relate to brainstem and proximal spinal cord compression and can include difficulty swallowing, choking, hoarseness, central apnea, disordered breathing, opisthotonos, and even sudden death. Many children with myelomeningocele also have cranial nerve abnormalities that lead to problems such as strabismus. The presence or development of hydrocephalus is extremely common. It is caused by abnormal cerebral spinal fluid flow pattern, which leads to enlargement of the ventricular system and pressure on the surrounding brain tissue. Up to a quarter of infants born with myelomeningocele have evidence of hydrocephalus before or at the time of birth. After primary closure of the back, most infants develop some amount of ventriculomegaly, but not all of these children require ventriculoperitoneal shunting for hydrocephalus. Additional clinical features of hydrocephalus include a bulging fontanel, crossing growth chart curve trajectories for head circumference, cranial nerve dysfunction such as sixth nerve palsy, sunsetting eyes (paralysis of upward gaze), vomiting, headache, irritability, and lethargy. These signs and symptoms are also indicators of possible shunt malfunction in children with ventriculoperitoneal shunts and require immediate evaluation. When shunt failure occurs, progression of symptoms can lead to loss of consciousness, papilledema, abnormal pupillary responses, and deterioration to death.

Children with myelomeningocele can have a host of other intracranial abnormalities, including partial dysgenesis of the corpus callosum, cortical dysplasias, abnormal cortical thickening in frontal regions and reduced thickness in posterior regions, reduced cerebellar size, and limbic track anomalies. Seizures are common among individuals with myelomeningocele and occur more frequently among children with higher lesion levels, shunts, and supratentorial brain abnormalities. Intellectual impairment is also more frequent among children with higher-level lesions and brain malformations compared with other children with myelomeningocele. Nearly three-fourths of children with myelomeningocele have IQ scores within the normal range. Children without hydrocephalus tend to have higher IQs and better executive functioning and memory. The cognitive phenotype of myelomeningocele is characterized by relative strengths, usually in language skills, and weaknesses, usually in visual-perceptual and mathematic skills. For example, many children with myelomeningocele are noted to have a “cocktail personality” with strong verbal fluency. In the classroom, neurocognitive problems can manifest as inattention and distractibility, poor task completion, disorganization, poor problem-solving skills, poor memory and comprehension, and emotional lability.

## MANAGEMENT

### Treatment Approach

The overall goals of treatment are to maximize health, well-being, and independence and to minimize disability.

The Institute of Medicine has defined health in childhood as “the extent to which children are able or enabled to a) develop and realize their potential, b) satisfy their needs, and c) develop the capacities that allow them to interact with their biological, physical, and social environments.” When thinking about health from this perspective for children with myelomeningocele, a helpful framework is the International Classification of Functioning, Disability, and Health. In this framework, health conditions interact with personal and environmental factors to affect functioning. Medical interventions, social supports, and community services can substantially influence the experience of disability for children with myelomeningocele. Achieving the aforementioned goals of maximizing health and minimizing disability for children with myelomeningocele requires diligent surveillance, careful and thoughtful interventions, and a strong interdisciplinary team. Because of the complex nature of myelomeningocele, children benefit from a team of health care providers offering coordinated comprehensive care in conjunction with the primary care medical home and community-based supports.

### Specific Treatments

Closure of the myelomeningocele lesions is of primary concern. Closure should be performed by an experienced pediatric neurosurgeon in a tertiary care setting with a neonatal intensive care unit familiar with the management of myelomeningocele. Some centers are now offering fetal repair of myelomeningocele. A recent multicentered trial compared fetal repair (before 26 weeks’ gestation) versus standard postnatal repair and found improved motor function at 1 year of age and reduced need for shunting in the fetal repair group. Currently, only a few very specialized centers with maternal-fetal treatment programs specializing in multidisciplinary fetal surgery are fully capable of performing this procedure and providing ongoing care to mothers and fetuses. Although limited information is available on the long-term effects of fetal repair, more centers are offering the procedure, and it is expected to become more common. Another advance in fetal intervention is endoscopic closure, which may improve neurologic functioning but is also associated with high risks to the fetus. Clinical trials are necessary to determine the appropriateness of this intervention.

Despite the recent advances in fetal intervention, most infants undergo standard postnatal repair after elective cesarean delivery. These infants should be stabilized with their lesions protected. Antibiotics are given to reduce the risk for central nervous system infection. An infant born outside of a tertiary care center should be transferred for ongoing management after being stabilized and receiving antibiotics. Primary closure should occur within 72 hours of birth. The wound requires careful monitoring and protection with the infant lying prone or on its side. Monitoring for progression of hydrocephalus is necessary and accomplished through serial head ultrasounds and head circumference measurements and by paying close attention to the symptoms associated with hydrocephalus. Because many more infants are

discharged from the hospital without a shunt but with evidence of ventriculomegaly or hydrocephalus, ongoing monitoring for worsening hydrocephalus is necessary on an outpatient basis. In recent years, neurosurgeons have been advocating for watchful waiting because of the high shunt complication rate. Because there is no consensus on shunting criteria, reported shunt rates vary substantially by center from 50% to 95%. Although the standard management for hydrocephalus is shunt placement, some neurosurgeons are managing hydrocephalus with third ventriculostomies and choroid plexus cauterization. Success with this technique is variable. Therefore, third ventriculostomies are not considered part of the standard of care. Hydrocephalus symptoms requiring urgent shunt placement include rapidly increasing head circumference, stridor, new or worsening swallowing dysfunction, and central apnea.

Neonates should also be evaluated for clubfeet and may require casting or splinting before discharge. Hip ultrasounds should be conducted to determine hip positioning and the need for a Pavloc harness. A renal and bladder ultrasound should be conducted along with voiding cystourethrogramurodynamic studies to assess the anatomy and function of the voiding system. Vesicoureteral reflux can occur in newborns and, if left untreated, lead to kidney damage in infancy. Neonates with a hostile bladder or reflux should be started on a clean intermittent catheterization (CIC) program. Additionally, many centers take a proactive approach to bladder management by initiating CIC for all neonates. Other centers recommend watchful waiting before initiating CIC, but this puts the child at risk for irreversible renal changes as a result of late intervention and may be more difficult for children and families to accept as part of their daily routine. Before discharge home for the first time, neonates should be assessed for safe swallowing, and a physical therapist should be consulted to teach the family a home program that involves stretching, positioning, and splint management (if they were prescribed). The infant should be referred to early intervention services and other community programs. Families should be supported as they adjust to the responsibilities of caring for a child with multiple medical issues.

## ONGOING CARE

### Follow-up

Ideally, all children with myelomeningocele should receive their primary care in a medical home along with coordinated care in an interdisciplinary spina bifida clinic that includes pediatric rehabilitation medicine and/or developmental pediatrics, neurosurgery, orthopedic surgery, urology, social work, nursing, physical and occupational therapies, and nutrition, with ready access to neuroradiology services; plastic surgery; pulmonary, endocrinology, neuropsychological testing; cognitive and speech therapy; and dysphagia therapy. Many children may live far away from a coordinated interdisciplinary clinic, requiring the pediatrician to take a more hands-on approach. Additionally, many interdisciplinary clinics do not have the

full complement of providers listed previously and refer to some subspecialists on an as-needed basis.

### Functioning and Development

One of the ongoing goals of care is minimizing disability or, more positively framed, maximizing function. This is achieved through aggressive medical management, the prevention of secondary conditions and complications, and attention to the developmental needs of the child in the context of the family and community. It should be expected that children with myelomeningocele will be delayed in their attainment of some developmental milestones and that certain milestones may never be achieved in some circumstances. It is important to work toward developmentally appropriate skills and make accommodations to maximize function despite existing limitations. Therapeutic goals should be discussed with the family and the treating therapists, and progress toward these goals should be monitored with an eye toward functional independence. Many children with myelomeningocele require adaptive equipment, such as lower extremity braces and mobility devices to help them achieve independent mobility. An orthotist familiar with pediatric bracing should be involved and work closely with the physical therapist and pediatric physiatrist to determine the best bracing options for each child.

When considering the developmental skills of a child, it is helpful to consider them by domain (self-care, mobility, cognition, and social skill development). Children develop self-care skills as they age. These skills are referred to as activities of daily living (ADLs) and include feeding, grooming, bathing, dressing, toileting, and bowel and bladder management. By age 7 years, typically developing children should be independent with these skills. Older children also learn instrumental ADLs (IADLs), such as being able to prepare meals, go shopping, and perform housekeeping tasks. The child with myelomeningocele may have difficulties with ADLs and IADLs because of neurologic or cognitive impairments, limited access to adaptive equipment and therapies, or lack of encouragement to learn independent skills in the home environment.

As described previously, impairments in mobility are extremely common among children with myelomeningocele. The neurologic motor level of the lesion is a strong predictor, but other factors certainly influence mobility. For most families, ambulation is a clear goal, but for some children, wheelchair mobility will offer more independence. Cognition, communication, and social skill development are also influenced by several factors, some of which are amenable to intervention. Children with myelomeningocele who exhibit difficulty in academic settings benefit from focused classroom adaptations as part of their individualized education programs. Some children may need extensive neuropsychological testing to elucidate specific neurocognitive deficits. In addition, some children need behavioral therapy or counseling to optimize social functioning. Generally speaking, children with myelomeningocele with hydrocephalus and higher lesion levels are at risk for not achieving independence in their day-to-day lives, owing to the more extensive nature of their impairments. These children

often require more adaptations and assistance to achieve optimal functioning.

As children with myelomeningocele age, they face the same developmental and social challenges that all children face. Despite the universal nature of growing up, children with myelomeningocele face special challenges. These challenges are physical and social in nature. Many children with myelomeningocele experience barriers to independent functioning and full participation in society. It is important to note that children with myelomeningocele have higher than typical rates of depression and anxiety. The pediatrician should be proactive in helping to address barriers to participation and should screen patients with myelomeningocele for mental health concerns. In addition, the pediatrician should be attentive to family functioning. Families of children with myelomeningocele can experience substantial social and financial effects and may benefit from referrals to supportive services.

### Neurologic

As detailed previously, children with myelomeningocele have alterations to their brains and spinal cords that are associated with a host of consequences. The neurologic follow-up for children with myelomeningocele should be ongoing. As early as possible, a neurologic level should be assigned. Many children have spotty sensation and varying degrees of motor control, which make assigning a level challenging. Nonetheless, documentation of neurologic function is essential because children can experience decrements in neurologic functioning related to complications such as tethered cord, hydrocephalus, worsening of the Chiari malformation, and syringomyelia. Routine monitoring of neurologic function can help identify developing problems and provides a baseline for comparison when new symptoms emerge.

Monitoring for hydrocephalus in infancy requires routine measurements of head circumference, assessing the fontanel for fullness, and obtaining serial head ultrasounds. In situations in which the infant's head is growing out of proportion with weight and length or is crossing percentiles on the growth curve chart, the neurosurgeon should be actively involved and the child monitored for acute symptoms of hydrocephalus. The decision to shunt hydrocephalus is usually made in infancy, although children can have progressive hydrocephalus. If concerns for hydrocephalus exist after infancy, computed tomography (CT) or rapid-sequence MRI should be ordered to assess the size of the ventricles. Symptomatic hydrocephalus is an indication for urgent evaluation by a neurosurgeon for cerebrospinal fluid diversion. Similarly, children with shunted hydrocephalus may develop shunt malfunctions or infections and require urgent intervention by neurosurgery to prevent clinical deterioration. If the clinical case is suspicious for shunt malfunction, a shunt series and CT or rapid-sequence MRI should be ordered. Pediatricians should also look out for the development of symptoms from the Chiari malformation. The infant or child with a symptomatic Chiari malformation may experience respiratory problems, swallowing difficulties, and cranial

nerve dysfunction. Use of MRI is necessary to characterize the Chiari malformation. A child with new-onset Chiari malformation symptoms should be evaluated for worsening hydrocephalus and syringomyelia. Management of hydrocephalus is important before performing a Chiari malformation decompression.

As described previously, in addition to the Chiari malformation, children with myelomeningocele can have other intracranial abnormalities that can significantly affect functioning. Because children with myelomeningocele are at increased risk for seizures, pediatricians should make sure to elicit any concerns about seizures. If seizures are suspected, a neurologist should be consulted for a workup that includes neuroimaging and electroencephalogram evaluations.

Essentially all children with myelomeningocele have evidence of spinal cord tethering on neuroimaging, but most do not develop symptoms. About 25% of children aged 2 to 8 years develop tethered cord symptoms. Urologic symptoms include changes in bladder habits, repeated urinary tract infections, upper tract dilation, and vesicoureteral reflux. Children also usually present with other neurologic symptoms such as worsening weakness, changes in lower extremity tone, or worsening foot deformities. Children with symptomatic tethered cords should be sent for imaging and then referred to neurosurgery for management. Although the untethering procedure is relatively straightforward, many children have retethering because of the formation of scar tissue and their pre-existing anatomic abnormalities. Therefore, most neurosurgeons proceed with caution when considering a second untethering.

Ongoing monitoring and management of neurogenic bowel and bladder are necessary throughout the life course. The level of intervention needed for each child varies greatly, but all children with neurogenic bladder need to be monitored because of the possibility of kidney damage from vesicoureteral reflux. The urologist will recommend a schedule for routine renal and bladder ultrasounds as well as voiding cystourethrograms. It should be noted that the presence of spontaneous voiding does not indicate normal bladder activity. As mentioned earlier, not all individuals are placed on CIC in infancy. However, the status of the bladder may change over time, requiring the use of CIC to maintain a low-pressure bladder and prevent kidney damage. The use of CIC also helps children with neurogenic bladders achieve social continence. By the age of 5 years, children are capable of learning how to perform their own catheterizations. In addition to the use of CIC, many children are placed on medication to assist with urine storage. This helps protect the renal system and can help children stay dry in between catheterizations.

The 2 main issues children with myelomeningocele face with respect to neurogenic bowel are constipation and incontinence. Most children have slower fecal transit times, which can lead to constipation. A diet rich in fiber is helpful in the management of constipation, but many children require promotility agents to improve transit times. In addition to constipation, children with a lower motor neuron colon have frequent fecal incontinence. For these children, manual

removal of stool on a regular basis can help with incontinence. For children with upper motor neuron colons, assistance with stool output is often required for successful evacuation. A suppository or enema, with digital stimulation near the internal anal sphincter, helps bring the stool into the rectum for evacuation. Some children can have successful bowel movements with the use of digital stimulation alone and do not need a rectal medication as part of their bowel program. In general, to achieve fecal continence and manage constipation, children should have bowel routines that include a regular diet rich in fiber, medications for motility if needed, and a plan for regular evacuation of stool. Children who are unable to achieve continence with their bowel program may be considered for surgery to create a conduit from the abdominal wall to the colon for the use of an antegrade colonic enema. Because surgery is not without risks, the child's bowel program should be optimized before surgery is considered.

### **Orthopedic**

The orthopedic issues are either lower extremity or spinal in nature. In the neonatal period, as described previously, infants may require management for congenitally dislocated hips and foot deformities. As children age, they may require additional orthopedic interventions. Notably, however, the management of the subluxed hip has changed substantially over the past decades because of the limited utility of surgical intervention. More important to a successful gait are the prevention of hip flexion contractures and the use of bracing and therapeutic interventions to maximize strength and function. Children may also need interventions for management of abnormal rotational forces and ongoing foot deformities. Although the Ponseti method may be effective for clubfeet in infancy, many children with myelomeningocele have relapse after initial management and may require soft tissue releases and, in the more severe cases, bony surgical interventions. With or without surgical intervention, most children with myelomeningocele require orthotics for maintenance of foot positioning and to assist with gait optimization. Most children with myelomeningocele do not have spasticity but are at risk for the development of contractures at the hips, knees, and ankles. A proactive approach that focuses on maintaining range of motion is important. In some cases, orthopedic release of contractures is warranted.

Most children with myelomeningocele develop spinal curvatures (scoliosis or kyphosis or both) as they age. Some infants are born with substantial curvatures at birth that progress during childhood. The development of spinal curvatures is correlated with the presence of congenital vertebral abnormalities such as hemivertebrae or wedge vertebrae, higher lesion level, higher neurologic motor level, syringomyelia, and tethered cord. Rapidly progressive curves should prompt the medical care team to consider neuroimaging for syringomyelia or tethered cord. In these cases, neurologic function may be deteriorating, and neurosurgical intervention may be warranted before orthopedic intervention. Goals for management of spinal curvatures include preventing the progression of the

deformity, achieving a solid fusion with a level pelvis for improved sitting tolerance, and maximizing functional independence. The indications for operative intervention are not clearcut, but in general, if the scoliotic curvature is rapidly progressing and conservative management is ineffective, surgery is warranted. For many surgeons, the presence of scoliosis greater than 50 degrees is an indication for surgery. In recent years, orthopedic surgeons have started using grow rods or the vertebral expandable prosthetic titanium rib procedure to address scoliosis but preserve growth. Anticipatory guidance before surgery is important because children undergoing operative intervention for either scoliosis or kyphosis are at risk for a host of complications, including infection, skin breakdown, loss of functional skills, loss of sensation or motor control, and pseudarthrosis. Immediately after surgery, many children are prescribed activity restrictions that can necessitate more assistance with transfers, self-care, and mobility. Also, children may need changes to their seating systems and other equipment. In the immediate postoperative period, consultations with physical and occupational therapy can assist in planning adaptations and training parents in biomechanically safe techniques for transfers and assisting with care. Plans should be made to address missed school and returning to school with activity restrictions. After restrictions are lifted, children should engage in a therapeutic program that focuses on restoration and improvement of function.

### **Skin**

Special attention to the skin covering the insensate areas of the body is essential throughout the individual's life. Parents of children with myelomeningocele should be taught about the risks for skin breakdown and how to prevent it. When children are old enough, they should be taught to do regular skin checks and pressure relief exercises if they use a wheelchair or stay in one position for an extended period of time. Just 2 hours of immobility can restrict blood flow enough to cause skin breakdown. The National Pressure Ulcer Advisory Panel classifies skin breakdown into 4 stages. Stage 1 is characterized by intact skin with nonblanching erythema. In stage 2 breakdown, the skin is open and the dermis is damaged or the area is covered by a blister. Stage 3 breakdown involves the subcutaneous tissues, and stage 4 extends down to muscle, bone, or tendons. The best management for skin breakdown is prevention because healing can be prolonged and the treatment can limit the individual's activities. The first and most important tenet of treatment is eliminating the cause of the breakdown and relieving the pressure on the wound. Debridement of dead tissue may be necessary, in addition to keeping the wound clean and protected from possible infections. Depending on the severity and location of the wound, a plastic surgeon may need to be consulted for surgical management.

### **Respiratory**

Disordered breathing is frequently under-reported and under-recognized by health care professionals. Especially in the very young child with myelomeningocele,

central respiratory dysfunction is of concern. Because of hydrocephalus and the Chiari II malformation, infants and young children can experience vocal cord paralysis and central hypoventilation. In severe cases, infants and young children may present with stridor, increased work of breathing, and apneic episodes. These patients need urgent intervention, usually consisting of placing a shunt or replacing the malfunctioning shunt and considering Chiari malformation decompression. In older children, respiratory problems may also be a sign of shunt malfunction. Children with myelomeningocele may also have restrictive lung disease from poor chest wall compliance, which worsens with progressive scoliosis. Sleep-exacerbated respiratory dysfunction may be identified on sleep study after identification of symptoms such as daytime fatigue, attention difficulties, frequent awakening during the night, or snoring with or without respiratory pauses. Children with severe respiratory dysfunction may require a tracheostomy and assistive ventilation if other interventions are not successful.

### Endocrine

Children with myelomeningocele are at risk for a host of endocrine abnormalities. An impressive percentage of children with myelomeningocele are overweight or obese. The risk for obesity is increased for nonambulatory children with higher lesion levels. Prevention of obesity is an important goal. Anticipatory guidance about aerobic exercise and healthy eating should be a part of every health maintenance visit. Some children may require adaptations to allow them to participate in physical activity that adequately raises their heart rate for aerobic exercise. Children with myelomeningocele are also at risk for early-onset type 2 diabetes and should be screened appropriately. Precocious puberty is more common in girls with myelomeningocele because hydrocephalus can disrupt the hypothalamus. If early pubertal development is noted, laboratory studies should be performed and the child referred to an endocrinologist. Some children with myelomeningocele also have growth hormone deficiency, which can contribute to short stature. In addition, nonambulatory children with myelomeningocele are at risk for decreased bone density resulting from decreased weight bearing. Children may be monitored with bone density testing if treatment would be initiated. Pathologic fractures are unfortunately relatively common in this population. Because children with myelomeningocele may be insensate, they may not know that they have a fracture. New deformities, swelling, and warmth in a limb should prompt an investigation for an occult fracture. In the face of a pathologic fracture, interventions for low bone density should be considered.

### Latex Allergies

All children with myelomeningocele are considered latex sensitive, and about 50% develop latex allergies. Latex should be avoided by all children with myelomeningocele. This means that certain toys, household objects, and medical equipment should be avoided. Parents should be provided a list of items to avoid and the children educated as they mature. If a latex allergy

is suspected, allergy testing should be performed and an epinephrine autoinjector (EpiPen) prescribed. There is also some cross-reactivity with bananas, kiwi, and avocado, so these fruits should be avoided in the latex-allergic child.

## COMPLICATIONS

Myelomeningocele should be considered a nonprogressive condition with multisystem involvement requiring vigilant monitoring and management. Changes to the child's functioning warrant investigation. In many cases, the pediatrician will need to engage a surgical or medical subspecialist in the workup and management. Some complications are urgent and life threatening, including shunt malfunctions and infections and symptomatic Chiari malformations. Some complications are not urgent but life threatening, including progressive pulmonary compromise from scoliosis and renal failure. Still other complications may be urgent but not life threatening, including tethered cord or a syrinx in the thoracolumbar spine.

## PROGNOSIS

The survival rate for children with myelomeningocele has drastically improved in the past 50 years. Routine use of shunting for hydrocephalus has markedly improved long-term survival, as has routine CIC. Despite recent improvements, the risk for death in individuals aged 5 to 40 years with myelomeningocele is 10-fold higher than the general population, and most of these deaths are unexpected. Just as there have been improvements in survival, there have been improvements in functional outcomes. Nonetheless, individuals with myelomeningocele frequently experience substantial disability. Prognosticating disability is challenging because it is multifactorial. Initial severity, medical complications, personal and family preferences, and social factors all contribute to the experience of disability. Many parents ask if their child with myelomeningocele will walk. The answer to this question is almost always yes with a lot of caveats. Except for children with very high lesions, the motivated child can walk. For children with high lumbar and lower thoracic lesions, walking may require extensive bracing, the use of an assistive device, intense physical therapy, and high energy expenditure, but it can often be achieved. For the child with a mid-lumbar lesion, walking is often achieved with bracing and crutches. The child with low lumbar or sacral lesions may not require any assistive device to ambulate successfully.

## PREVENTION

At this time there is no way to completely prevent myelomeningocele, but folic acid supplementation has been effective in decreasing the risk for myelomeningocele. The American Academy of Pediatrics and the Centers for Disease Control and Prevention recommend that all women of childbearing age receive 0.4 mg of folic acid daily. Women with neural tube defects or first-degree relatives with neural tube defects should take 4 mg of folic acid daily.

### WHEN TO REFER

- If meningocele is discovered prenatally, the mother should be referred to high-risk obstetrics and to a tertiary medical center that specializes in the care of infants with congenital malformations.
- If meningocele is diagnosed prenatally before 25 weeks, and the mother is interested in pursuing fetal repair, the mother should be referred to quaternary medical center with a multidisciplinary team specializing in fetal surgery.
- Infants born with meningocele should be referred to a tertiary medical center that specializes in the care of these infants.
- All infants born with meningocele should be monitored during childhood by a multidisciplinary team that includes experts in pediatric rehabilitation child development, neurosurgery, orthopedics, urology, neuropsychology, orthotics, social work, nursing, and physical and occupational therapies.
- Referral to an early intervention program should be accomplished early on.
- Parents of a child with meningocele who are considering subsequent pregnancies should be referred to genetic counseling.
- Individuals with meningocele who are considering having children should be referred to genetic counseling, and young women with meningocele considering pregnancy should be referred to high-risk obstetrics.

### WHEN TO ADMIT

- The child is acutely ill and cannot be managed at home.
- There is concern for sepsis or shunt infection.
- The child requires surgical intervention.

### Chapter 333

## SPINAL DEFORMITIES

John T. Anderson, MD

### SPINAL CORD AND VERTEBRAL EMBRYONIC DEVELOPMENT

Genetic abnormalities and teratogen exposure occurring during the embryonic period can adversely affect normal differentiation of the musculoskeletal system, resulting in malformations of the extremities or the spine. Formation of the defined spinal column occurs from the fourth through the sixth week of gestation. Somatic mesodermal tissue surrounding the notochord differentiates into a less cellular and dense upper portion and a more dense and cellular lower portion, which cleave together. The intervertebral disc

develops at the site of the cleavage. The notochord, which is contained within the newly joined primitive vertebral bodies, degenerates, and specific portions at the site of cleavage become the nucleus pulposus of the intervertebral disc. The neural arches and ribs develop from the more dense portions of the somite, and the vertebral body develops from the less dense portions.

Chondrification begins in the primitive mesodermal vertebrae during the sixth week of pregnancy and progresses rapidly to form cartilaginous models of the vertebral body by the end of the first trimester. Ossification of the cartilaginous models begins during the second trimester. The ossification of each side of the neural arch and of the body at each level proceeds separately. In the neonate, the ossified vertebral body and neural arches at each level are clearly visible radiographically, separated by the neurocentral synchondroses. The neural arches posteriorly are also separated by a cartilaginous synchondrosis. The ossification centers of the neural arches and body coalesce during the first 3 to 7 years of postnatal development, whereas the synchondroses of the neural arches close at approximately 3 years of age.

The first and second cervical segments are distinct from the remainder of the spinal column. The first cervical vertebra lacks the physical form characteristic of other vertebrae, having instead only a narrow anterior arch. This arch is not ossified at birth or during the neonatal period but is most often visible by 1 year of age.

Errors in the embryologic sequence of the spine cause several congenital defects of the spinal column and spinal cord. These errors range in severity from isolated hemivertebrae to complex errors of vertebral formation and segmentation associated with defects of the neural tube or spinal cord. When such errors result in asymmetrical vertebral formation or produce asymmetrical vertebral growth potential, structural spinal curves such as congenital scoliosis or kyphosis develop.

Malformations of the head and neck, especially the internal and external auditory apparatuses, maxillae, and mandibles, occur frequently in children with high thoracic and cervical curves. The association of a short neck, low posterior hairline, and restriction in neck motion caused by the congenital fusion of cervical vertebrae represents Klippel-Feil syndrome. Renal anomalies, the congenital elevation of the scapulae (ie, Sprengel deformity), impaired hearing, and congenital heart disease are common associated anomalies in affected patients. The VATER syndrome (vertebral defects, imperforate anus, tracheoesophageal fistula, and radial and renal dysplasia) and the VACTERL complex (see later discussion) underscore the complex nature of the relationships between the rapidly evolving organ systems and the musculoskeletal system during the first trimester of pregnancy.

## SPINE ABNORMALITIES

### Postural

Back pain in children is, occasionally, a sign of an underlying disorder. Postural abnormalities may or

may not indicate an underlying spine disorder. The challenge to the physician is to determine whether the child's posture or pain is caused by an underlying musculoskeletal disorder or is merely a habit that alters—exaggerates, increases, or decreases—the normal spinal alignment. The cervical and lumbar spine are normally lordotic, and the thoracic spine is kyphotic. These sagittal plane curves (as viewed from the side) determine a person's sagittal balance. When viewed from the front, or coronal plane, the spine should be straight, with the head balanced over the pelvis. Abnormal curvatures and protrusions merit careful investigation. If either condition is excessive, progressive, or painful, then concern is appropriate. Scoliosis, a side-to-side curve, is always abnormal. A classification of spinal deformities is provided in Box 333-1.

### Congenital Malformations

When a newborn is held prone in the examiner's palm, the infant's spine falls into slight flexion, allowing detection of meningocele, scoliosis, or hyperkyphosis. An underlying spinal dysraphism may be indicated by a hair tuft, dimple, discoloration, or palpable spina bifida lamina defect (see Chapter 332, Spina Bifida).

### Congenital Scoliosis

Congenital scoliosis is caused by abnormal in utero vertebral development. These anomalies are caused by failure of formation or failure of segmentation (Figure 333-1 and Figure 333-2). The anomalous vertebrae lead to asymmetrical spinal growth that manifests as scoliosis. Congenital spinal anomalies are sometimes related to cardiac or urologic abnormalities that develop during the same period. Therefore, it is recommended that these children receive a renal ultrasound and, if clinically indicated, a cardiac evaluation. Overall, this disorder shows progression in 75% of cases, although this can vary greatly depending on the type of anomaly present. Children with a unilateral unsegmented bar and a contralateral hemivertebra (up to 10 degrees/year progression) have the poorest prognosis, followed by unilateral unsegmented bar (5 degrees/year), 2 unilateral fully segmented hemivertebrae (3 degrees/year), and unilateral fully segmented hemivertebra (1–2 degrees/year). The least severe progression is seen with block (bilateral nonsegmented bar) and wedge vertebrae.

The management of congenital scoliosis requires frequent clinical and radiographic follow-up to detect progression. Referral to a spine specialist is recommended. As is the case for most spinal deformities in children, the risk for progression is highest during periods of accelerated growth. This occurs during the first 2 years of life and during the adolescent growth spurt. When the deformity is located near the middle of the spine, the segments of the spine above and below often attempt to compensate by curving in opposite directions. The result is a balanced spine. Treatment may be unnecessary. When, however, the anomalous vertebra is at the base of the spine (low lumbar or lumbosacral), progression will lead to continued oblique growth of the lumbar

spine that causes marked truncal imbalance. Many surgeons now advocate excision of the anomalous vertebra and a short segment fusion to prevent progression. Congenital scoliosis affecting the upper thoracic spine or cervicothoracic junction is very common, but, fortunately, does not typically cause large curves. However, it can elevate the shoulder on the convex side of the curve and cause an oblique take off of the cervical base, which results in head tilt. Obviously, this can be a significant cosmetic concern for the child. For progressive deformities, the treatment can involve many different strategies, depending on the type of anomaly (isolated or diffuse), the location of the deformity, the age of the child, and the degree of deformity. Current emphasis

has been placed on treatment methods that avoid early and/or extensive spinal fusion in the hope of affording these often very young children the opportunity to gain additional chest wall growth and pulmonary development.

A certain subset of patients with congenital scoliosis can develop deformities that lead to a condition termed *thoracic insufficiency syndrome*. This is defined as the inability of the thorax to support respiration or lung growth. The classic description is a patient with congenital scoliosis and fused or absent ribs on the concave side of the deformed spine. The deformity can inhibit chest wall growth and thus lung development. This may ultimately lead to restrictive lung disease and eventual cardiopulmonary

**Figure 333-1** Congenital scoliosis. Failure of formation: A, wedge vertebra; B, fully segmented hemivertebra; C, partially segmented hemivertebra; D, unsegmented hemivertebra.

**Figure 333-2** Congenital scoliosis. Failure of segmentation: A, block vertebra; B, unilateral bar; C, unilateral bar with contralateral hemivertebra.

failure. Therefore, referral to a pulmonologist is often indicated to optimize pulmonary health. The vertical expandable prosthetic titanium rib (VEPTR) was developed to treat this particular disorder. The device can be anchored to the ribs, spine, and/or pelvis to simultaneously expand the chest wall and control the spine deformity. The device is traditionally lengthened every 6 months. The use of this device has gained in popularity as an alternative to early spinal fusion that halts chest wall development and thus additional lung growth. It can also be used to treat congenital chest wall deformities secondary to conditions such as Jeune syndrome and Jarcho-Levin syndrome.

### **Congenital Kyphosis**

Similar to congenital scoliosis, congenital kyphosis is caused by either a failure of segmentation or failure of formation. The anomaly typically occurs at the

**Figure 333-3** Axial computed tomography image of spina bifida occulta of S1.

anterior aspect of the spine. This causes asymmetrical growth, with more growth occurring posteriorly. Thus, with time, a sagittal plane deformity (as viewed from the side) develops that can cause hyperkyphosis of the thoracic spine and loss of lordosis in the lumbar spine. The more severe deformities are usually recognized in the neonate, and they rapidly progress thereafter. The less obvious deformities may not appear until several years later. After progression begins, it does not cease until the end of growth. The most important factor regarding congenital kyphosis is the possibility that a progressive deformity in the thoracic spine can result in paraplegia. This potential outcome is usually associated with failure of the formation of the vertebral body. Congenital kyphosis, for the most part, is a surgical problem. This can take on many forms depending on the degree of deformity, the child's age, and his or her neurologic status. Severe degrees of kyphosis can lead to restrictive lung disease and respiratory symptoms such as dyspnea.

### **Spina Bifida**

*Spina bifida* is a rather nonspecific term often used to describe children with myelomeningocele. This should not be confused with spina bifida occulta, which is usually an incidental radiographic finding in an otherwise normal child. Spina bifida occulta is an incomplete formation of the posterior neural arch, usually at L5 or S1 (Figure 333-3). It generally does not involve the underlying neural elements and has no effect on the child's health. However, this should not be ignored if the area has an overlying sinus, lipomatous lesion, or hemangioma, indicating a possible underlying dysraphism.

Both meningocele and myelomeningocele involve a failure of posterior neural arch formation of the dural layers and of the overlying skin. Thus meninges (meningocele) or meninges and neural elements (myelomeningocele) are exposed. Both conditions usually warrant early surgical closure to prevent

central nervous system infection. Because meningocele does not involve the neural elements, these children are generally not prone to bowel, bladder, and lower extremity paralysis, whereas this is usually the case for children with myelomeningocele. These children are at high risk for hydrocephalus and Arnold-Chiari II malformation, most of them requiring ventriculoperitoneal shunt insertion shortly after defect closure. Although the exact etiology of Arnold-Chiari II malformation is debatable, it is generally thought to be secondary to progressive caudal migration of the hindbrain, resulting from the low-pressure gradient caused by the open myelomeningocele. This leads to impaired cerebrospinal fluid dynamics and, ultimately, hydrocephalus. These children are also at risk for other central nervous system-related problems, such as hydromyelia, diastematomyelia, and tethering of the spinal cord.

Myelomeningocele is a severe disorder affecting many different systems, requiring a multidisciplinary team model to coordinate a child's care and optimize a his or her health. Spinal care is often complicated by many factors: allergy to latex; lack of protective sensation; increased risk of postoperative wound infections; major joint contractures; and poor soft tissue coverage over the spine.

Spinal deformity is common in myelomeningocele. It is present in up to 70% of children. With thoracic-level paralysis, the incidence is as high as 94%. Therefore, all children should be periodically screened. It can present in many different forms, including idiopathic-type curves, long-sweeping curves typical of neuromuscular disease, congenital scoliosis or kyphosis related to vertebral anomalies, and severe lumbar level kyphosis. Children should be assessed for how the deformity is affecting their life. Treatment should be individualized to the child. It may be wise to delay treatment as long as possible in ambulatory children because surgical treatment may affect their ability to ambulate efficiently. On the other hand, a nonambulatory child who is having problems maintaining proper wheelchair sitting balance, resulting from a large curve causing pelvic obliquity and severe trunk shift, may be better suited for more expedient surgical care—particularly if the child is not able to use his or her hands because they must be used to support the trunk. In general, it is appropriate to attempt bracing in mild curves (25 to 45 degrees) in a skeletally immature child. This may slow the rate of progression. Children with curves that progress beyond 45 degrees can be considered for surgical treatment; but, again, the child's individual needs must be considered when making this decision. As with scoliosis related to other etiologies, it is desirable, when possible, to delay definitive fusion in a child with substantial growth remaining to allow for ample chest wall maturity to occur.

Lumbar kyphosis is a very difficult deformity to manage in this patient population. It can present very early and create problems with defect closure and skin integrity. It is more common in lower thoracic and upper lumbar levels of paralysis. In the event of skin breakdown over the prominence, an attempt should be made to modify the child's activities and seating

supports to remove pressure from the area. With progressive deformities, surgical treatment is often the only alternative. This usually involves removing a portion of the spine (kyphectomy) and performing an instrumented spinal fusion. The assistance of a plastic surgeon may be necessary for soft tissue management and wound closure.

### **Larsen Syndrome**

Larsen syndrome is an autosomal-dominant osteochondrodysplasia. Recently, Larsen syndrome was shown to be caused by missense mutations or small in-frame deletions in the *FLNB* gene. These children have very marked orthopedic-related problems, including multiple dislocated joints, clubfeet, cervical kyphosis, and scoliosis. It is imperative that the cervical spine is evaluated early in this patient population. Cervical kyphosis and anterior-posterior dissociation can threaten the spinal cord. Furthermore, the presence of either needs to be recognized to avoid catastrophic events during intubation for other required surgical procedures.

Cervical kyphosis should be surgically treated if the spinal cord is under compression. This should be evaluated by magnetic resonance imaging (MRI). If cord compression is evident by imaging or physical examination findings, then posterior spinal fusion should be performed. Continued anterior spinal growth may correct the deformity with time.

Anterior-posterior dissociation can also be present in children with cervical kyphosis. This entails a lack of continuity between the anterior and posterior aspects of the vertebra through multiple wide pars interarticularis defects. This is best seen on computed tomography (CT). Simple posterior fusion will not adequately address this particular problem. Therefore, a long anterior-posterior fusion will be necessary. The abnormal portion of the spine must be fused to more normal areas.

Scoliosis is reported in 25% to 70% of children with Larsen syndrome. Onset is usually in the juvenile age group. Treatment is similar to juvenile idiopathic scoliosis. However, bracing must be recommended with caution because the chest wall plasticity associated with these children can be problematic. The pressure induced by the brace may cause chest wall deformities.

### **Goldenhar Syndrome—Ocular-Auriculo-Vertebral Spectrum**

Abnormalities in Goldenhar syndrome include a variety of ocular, auriculo, and vertebral anomalies, and thus was appropriately renamed *ocular-auriculo-vertebral spectrum* (OAVS). However, of note, the terms *Goldenhar syndrome* and *OAVS* are used interchangeably to describe this myriad of congenital anomalies.

The incidence of OAVS is rare; the prevalence is estimated to be approximately 1 in 45,000 live births. Male infants are affected more often than female infants, and the right side of the face or body (or both) is generally more commonly and severely affected than the left. OAVS has wide phenotypic variation, and, at present, no clear standard for diagnosis exists.

However, authorities generally agree that the spectrum includes 2 or more of the following abnormalities: ear malformations (including microtia and accessory tragi), low-set ears, hemifacial microsomia (including micrognathia), coloboma, and vertebral anomalies (fused or cervical hemivertebrae). Of these abnormalities, multiple accessory tragi in a preauricular-mandibular distribution is one of the more constant findings and is an important diagnostic clue to recognizing the syndrome. Multiple malformations, including congenital heart, brain, and renal disease, have been seen in small numbers of children with OAVS.

Abnormalities of the spine are present in up to 60% of this patient population. Congenital malformations as seen in children with congenital scoliosis are common. Therefore, children identified as having this syndrome should be routinely screened for spinal anomalies.

#### **Morquio Syndrome (Mucopolysaccharidosis Type IV)—Odontoid Dysplasia With Atlantoaxial Subluxation**

Mucopolysaccharidosis type IV (A and B) is also known as *Morquio syndrome*. This disorder consists of 2 forms with similar clinical findings and autosomal recessive inheritance. Mucopolysaccharidosis type IV-A results from mutations in the gene-encoding galactosamine-6-sulfatase, located at 16q24.3. Mucopolysaccharidosis type IV-B (a milder variant) is caused by  $\beta$ -galactosidase deficiency. The clinical features result from accumulation of keratin sulfate and chondroitin-6-sulfate. In both forms, mental symptoms are absent or only mildly present, a feature that distinguishes it from the other mucopolysaccharidoses. These children seem “normal” at birth but will present at 12 to 18 months of age with an “abnormal” appearance. The musculoskeletal findings may include joint laxity, short stature, pectus carinatum, genu valgum, pes planus, and enlarged joints. Corneal clouding is present in 50% of cases. These individuals often stand with their hips and knees flexed and their head thrust forward on a shortened neck.

Individuals with Morquio syndrome often present to the orthopedist with thoracolumbar kyphosis. Radiographically, they have flattened vertebrae with an anterior beak in the thoracolumbar spine (Figure 333-4). This may resolve with growth but may become progressive and eventually require surgical neural element decompression and spinal fusion.

The spinal manifestation most concerning in this population is atlantoaxial instability secondary to odontoid hypoplasia. This can cause upper cervical cord compression. These children present with difficulty walking. It is important not to ascribe this to their lower extremity problems. The potential for this problem should be evaluated before intubation for other surgical procedures with flexion-extension cervical spine radiographs. This is a surgical problem that, when present, needs to be addressed quickly. Morquio syndrome is also associated with pulmonary complications such as obstructive sleep apnea and restrictive lung disease. Therefore, referral to a pulmonologist is often indicated.

**Figure 333-4** Lateral radiograph of a child with Morquio syndrome. Note wedging of vertebrae with anterior beaking.

#### **VACTERL Complex**

VACTERL complex refers to anomalies of the vertebrae, atresias in the gastrointestinal tract, congenital cardiac lesions, tracheoesophageal defects, renal and distal urinary tract anomalies, and rib and limb lesions. The categorical breakdown of anomalies in a large series were as follows: vertebral (25%), anal, esophageal (or other gastrointestinal) atresia (15%), cardiac (33%), tracheoesophageal fistula (95%), urinary (renal dysplasia, urethral valves) (17%), and skeletal (16%). The overall incidence of infants born with 3 or more components of this spectrum is estimated to be 1 in 25,000 live births.

#### **Treatment Advances**

Several groups have reported exciting advances in spinal surgery techniques to correct deformities. Research concerning the successful implementation of growing rods has revived this technique as a viable option for preserving near-normal growth of the spine in both congenital and acquired disorders.

New techniques were also recently described, including vertebral body stapling that produces asymmetrical and corrective growth of the concavity of a deformity. This ultimately may prove to be a useful technique to treat children with scoliosis that continues to progress despite brace wear.

## Acquired Abnormalities

### Scoliosis

Acquired scoliosis can present in many different forms. It is very important that the treating physician make the correct diagnosis because treatment options vary depending on the etiology. The most common form of acquired scoliosis is idiopathic in nature. Although much has been done to elucidate the genetics contributing to this form of scoliosis, little is still known of its etiology. Traditionally, this form of scoliosis was classified as infantile (0 to 3 years), juvenile (4 to 10 years), and adolescent (>10 years). More recently, the term *early-onset scoliosis* has been used to classify children with the onset of deformity before age 5 years. Adolescent idiopathic scoliosis is the more common variety of the 3 and is the most common form of acquired scoliosis.

Acquired scoliosis can also occur in children with certain genetic and neuromuscular diseases. The treating physician must recognize when a child is at risk and appropriately screen for progression. Referral to a pulmonologist is recommended if there are concerns for restrictive lung disease.

Children particularly prone to developing progressive scoliosis are those with static encephalopathy, especially those with spastic quadriplegia. These children commonly develop large thoracolumbar or lumbar scoliosis that can affect their sitting balance (Figure 333-5). This type of spinal deformity can also cause marked pelvic obliquity. Unfortunately, little is known of the natural history of scoliosis in this patient population. The available literature is conflicting. It seems that these curves do tend to progress if they exceed 40 to 50 degrees before skeletal maturity. Treatment options vary depending on the overall health of the child, degree of truncal deformity, effect the spinal deformity has on the child's ability to function, and expectations of the caregivers. The effect of bracing on this type of scoliosis is controversial. However, at times it can be a useful modality to improve the child's sitting balance. Wheelchair modification can also be an effective measure. For curves that are progressive and causing functional limitations, particularly issues with wheelchair sitting, spinal fusion and instrumentation are sometimes necessary. These usually involve fusion to the sacrum with fixation to the pelvis to control pelvic obliquity. This is an extensive operation with significant risks, but with reports of very high caregiver satisfaction. Surgical intervention is sometimes warranted when scoliosis is causing severe restrictive lung disease.

### Infantile Idiopathic Scoliosis

Infantile idiopathic scoliosis presents before the age of 3 years. Most patients are boys with convex left curves. Females with convex right curves have a worse prognosis. It should only be diagnosed after all other etiologies are excluded. This type of scoliosis resolves spontaneously in most children. There are radiographic criteria to predict curve progression. For those that progress, the disease can significantly reduce life expectancy because of cardiopulmonary compromise. These curves can become quite large at a very young age. Treatment is difficult because of the

**Figure 333-5** Neuromuscular scoliosis with pelvic obliquity.

young age of the children. Early spinal fusion should be avoided to allow for continued chest wall and lung development. There are few data to suggest that bracing effects the natural history of the disease. More recently, serial casting has gained momentum as a means of controlling the deformity. There have been some reports of deformity resolution. If resolution is not accomplished or the deformity continues to progress, then surgical options that do not involve a formal fusion of the spine should be considered. Children with curves greater than 20 degrees should have total-spine MRI to rule out an underlying dysraphism.

### Juvenile Idiopathic Scoliosis

Juvenile idiopathic scoliosis is typically defined as scoliosis that presents in the 4- to 9-year age group. It presents during a time of relatively slow spinal growth. These curves can behave as either infantile or adolescent in nature. Up to the age of 6 years, the girl-to-boy ratio is equal and convex left curves are common. After the age of 6 years, girls are predominately affected and convex right curves are more common. Similar to children with infantile idiopathic scoliosis, those affected in this age group can rapidly progress and develop cardiopulmonary compromise. A recent study reported that children with curves

30 degrees or greater at the onset of puberty have a 100% chance of requiring surgery. Treatment is dependent on the age of the patient and the degree of progression. For curves exceeding 20 to 25 degrees, bracing can be instituted. It can also be attempted for larger curves in hopes of slowing progression to allow time for chest wall development. In a skeletally immature child, curves greater than 40 degrees can be considered for surgical treatment. Because of the young age of these children, recent emphasis has been placed on nonfusion instrumentation (growing rods) that controls the deformity but still allows growth. This allows the surgeon and child to postpone a definitive spinal fusion and instrumentation until the child achieves adequate chest wall and pulmonary development.

As with children with infantile idiopathic scoliosis, these children should have a total spine MRI to rule out an underlying spinal dysraphism.

### Adolescent Idiopathic Scoliosis

Adolescent idiopathic scoliosis (AIS) is the most common type of idiopathic scoliosis. It is defined as a lateral curvature of the spine of more than 10 degrees with vertebral rotation on a standing radiograph. Typically, the deformity is discovered when truncal asymmetry is noted. Adam's forward bend test is commonly used to assess the rib or flank prominence created by the scoliosis (Figure 333-6). A scoliometer measurement can be made of the angle of trunk rotation (ATR). A 7-degree ATR is often cited as the magnitude at which to initiate referral. The efficacy of school screening remains a controversial and debated topic.

It is critical that the treating physician rule out other etiologies because AIS is a diagnosis of exclusion. One should look for the presence of abnormal cutaneous findings, asymmetry of shoulder height and scapular prominence, waist line asymmetry, and iliac crest height discrepancy, which indicates a leg-length discrepancy. The child's feet should be assessed for asymmetry or deformity. For example, a child with a

**Figure 333-6** Adam's forward bend test.

unilateral high-arched foot (cavus foot) or a cavus foot with clawed toes may have an underlying neural axis abnormality (eg, syringomyelia) or nervous system disease (eg, Charcot-Marie-Tooth disease). The child should have a complete neurologic examination.

Patients with back pain should be questioned carefully to ascertain whether the pain is a serious problem or simply fatigue related. Certainly, children having pain that limits their ability to perform activities of daily living or engage in their usual activities should raise concern. Furthermore, pain that is associated with unexplained weight loss, malaise, night pain, fevers and chills, or neurologic complaints should be thoroughly evaluated.

Standard screening radiographs include upright posteroanterior and lateral views that include the cervical spine and pelvis. These should be obtained on 36-inch cassettes. The lateral radiograph should be taken with the elbows flexed in front of the child and hands positioned beneath the chin. The arms should not be flexed forward as is standard for a chest radiograph. Curves are measured with the Cobb measurement (Figure 333-7). Advanced imaging such as MRI or CT are appropriate in certain cases when an underlying neural axis or structural abnormality is suggested by the history, physical examination, or radiographs. Radiographic findings suggestive of an underlying

**Figure 333-7** Cobb angle measurement.

neural axis abnormality are convex left thoracic curves, double thoracic curves, triple curves, long right thoracic curves with an end vertebra (the last vertebra contributing to the Cobb measurement) caudal to T12, and curves with a high or low apex. These findings are even more concerning in boys. Additionally, thoracic curves that have normal kyphosis or hyperkyphosis on the lateral radiograph should raise suspicion of an underlying neural axis abnormality because thoracic scoliosis is normally a hypokyphosing or lordosing deformity.

It is thought that AIS is likely a genetically linked disorder, but the genetics of the disease have not been fully elucidated to date. Adolescent idiopathic scoliosis typically progresses during times of rapid growth, such as the adolescent growth spurt when children are at their peak height velocity (PHV). Therefore, it is important to determine where the children are in their development. For girls, the onset of menses is an important landmark, as is the development of axillary hair in boys. Both typically occur about 6 months before the PHV. Radiographically, it is useful to assess whether the triradiate cartilage is open or closed and the Risser sign (Figure 333-8). Typically, closure of the triradiate cartilage occurs after PHV; in boys, however, closure may signal the start of PHV. Immature children with a Risser grade of 0 or 1 and with curves exceeding 20 degrees have an approximately 70% chance of progression. A bone age radiograph (posteroanterior left hand radiograph) is often useful because a child's chronologic age and skeletal age can differ. A lateral radiograph of the elbow can also be useful in determining whether children have achieved their PHV (Figure 333-9).

The natural history of scoliosis depends on the degree of deformity, location of the curve, and skeletal maturity of the child. As for curve patterns, thoracic curves and double curves are most likely to progress in immature individuals. After skeletal maturity, thoracic curves greater than 50 degrees tend to progress at a rate of about 1 degree per year. Thoracolumbar

and lumbar curves may progress into adulthood even when below 50 degrees in magnitude. In general, curves less than 30 degrees at skeletal maturity tend not to progress. The effect scoliosis has on overall health is not well documented. Respiratory failure has been documented in adults with scoliosis greater than 110 degrees. However, according to a recent long-term follow-up study of 117 children with untreated scoliosis, most children reported good general health. They reported more back pain, but this did not seem to affect their ability to work or perform activities of daily living. Children with curves greater than 80 degrees tended to experience shortness of breath with activities more often, but this did not reach statistical significance.

Treatment of AIS depends on the age of the child and the curve magnitude. In general, brace treatment is initiated in skeletally immature children (Risser grades 0–2) with curves in the range of 30 to 45 degrees or with curves that progressed more than 5 degrees after presenting at 25 to 30 degrees. Individuals who have a Risser grade of 0 and a curve of 25 degrees or greater should be considered for bracing. The use of bracing seems to be supported by the current literature.

**Figure 333-8** Risser sign. The iliac crest apophysis ossifies, radiographically, from lateral to medial. Risser V equals skeletal maturity.

**Figure 333-9** Lateral elbow radiography in a 10-year-old girl. Note the present of two olecranon ossification centers, indicating that she is at peak height velocity.

For children who continue to progress beyond 50 degrees in the thoracic spine and perhaps 40 to 45 degrees in the thoracolumbar or lumbar spine, surgical treatment can be considered. The goal of the operation is to balance the trunk, while fusing the fewest levels possible, and obtaining a solid fusion to prevent progression. Many different approaches can be used, each having pros and cons, but most children undergo a posterior spinal fusion and instrumentation.

### Kyphosis

An excessive amount of thoracic kyphosis can occur for many reasons, including, but not limited to, spinal tumors, radiation, trauma, infection, or surgery (eg, after laminectomy). The most common cause of acquired kyphosis is an osteochondrosis known as Scheuermann disease (see Chapter 303, Osteochondroses), which occurs in 5% of the population. Scheuermann disease, by definition, involves wedging of 3 contiguous vertebrae more than 5 degrees (Figure 333-10). Alternatively, glucocorticoid-induced osteoporosis, caused either by supraphysiologic

levels of endogenous glucocorticoids (Cushing disease) or by exogenously administered glucocorticoids, can provoke kyphosis. Excess glucocorticoids often act to suppress bone formation and increase bone resorption, leading to trabecular bone loss, vertebral body collapse, and pathologic fractures and resulting in an increased propensity to kyphotic spinal malalignment. The most common site is in the lower thoracic vertebrae, but this condition can occur in any site in the vertebral column. The initial event is bulging of the intervertebral discs in the direction of contiguous vertebral bodies, which exerts pressure against the cartilage plates covering the bodies, causing thinning of the plates. This event interferes with endochondral bone formation on the growth surface of the plates, causing gaps that are the basis for the herniation of the disc into the bodies, isolating the apophyseal ossification center from the vertebral body. The disc space narrows, more so anteriorly, causing increased pressure on the anterior portions of contiguous vertebral bodies and impeding their longitudinal growth anteriorly, resulting in attendant kyphosis.

In children with Scheuermann disease, an aching pain aggravated by physical exertion is present in the affected part of the vertebral column, typically the thoracic or thoracolumbar spine. The affected area may be tender to palpation. Having the child assume a stooping position often causes the pain to increase. In many instances, the pain is so minor that the child first complains of pain caused by *poor posture*, and then the kyphosis is noted. Radiographs reveal a narrowing of the anterior disc space and defects on the surfaces of adjacent vertebrae at sites where the disc tissue penetrated the bodies. The prolapsed disc tissue, in time, becomes walled off by osseous tissue, forming a bulbous mass of extruded tissue appearing as an area of lucency in the affected body (Schmorl nodule). In some children, the condition can progress to cause severe deformity and dysfunction.

Treatment depends on the cause of the hyperkyphosis. Obviously, in cases of hyperkyphosis caused by medically related problems, the underlying source of the problem must be addressed. When spinal stability is compromised secondary to previous operation, tumor treatment, infection treatment, or trauma, the spine will need to be surgically stabilized. For children with maintained spinal stability and acceptable balance, casting or bracing may assist with pain management until the underlying problem is adequately addressed.

In children with Scheuermann disease who have adequate growth remaining, bracing may be useful. A physical therapy regimen focusing on spinal extensor and abdominal wall strengthening is reasonable and should be attempted for at least 6 months before entertaining any thought of surgical treatment. The indications for the surgical treatment of Scheuermann disease are limited. The natural history is generally benign. For children with kyphosis exceeding 70 degrees who have recalcitrant pain and a self-perceived unacceptable appearance, surgical treatment may be warranted. This typically involves an instrumented fusion procedure.

**Figure 333-10** Lateral radiograph of a child with Scheuermann kyphosis. Note wedging of the apical vertebra and end-plate irregularities or Schmorl nodes (superior aspect of T12).

### Back Pain

Although scoliosis and kyphosis can be painful, they are usually painless postural deformities. The pediatrician should be aware of several painful disorders related to spinal deformity (see Chapter 131, Back Pain).

### Spondylolysis and Spondylolisthesis

Spondylolysis is a defect in the continuity of the pars interarticularis, which is a strut of bone that connects the superior and inferior articular processes of a vertebra. In children and adolescents, it usually involves either L4 or L5 (Figure 333-11). In certain children, it may lead to forward slippage (listhesis) of the vertebral body, known as *spondylolisthesis*. The horizontal slippage usually involves the L5 vertebral body moving anteriorly in relationship to S1. However, this deformity can occur anywhere in the vertebral column. Both spondylolysis and spondylolisthesis can cause back pain. The pain may radiate to the buttocks, but true radicular symptoms are rare. The pain is usually activity related, worse when upright than when seated or supine. Because spondylolysis is fairly common in young athletes with low back pain, primary care physicians need to have a high index of suspicion with this group of children.

Trauma, causing disruption of the pars interarticularis, is thought to be the cause of spondylolysis in a genetically susceptible host. Gymnasts and other athletes (football front lineman) who repeatedly hyperextend the spine have a higher incidence of spondylolysis than the

general population. In adolescence and adulthood, the incidence is estimated at 6%. Current research emphasizes the role of spinopelvic balance in the pathogenesis and treatment of spondylolisthesis. Spondylolisthesis can progress in certain children, especially during times of accelerated growth; therefore, periodic follow-up is indicated in children 10 years of age or younger.

The physical examination may reveal tenderness in the lower back. The child may have tight hamstrings and, in the case of a high-grade slip (>50%), may assume a posture of leaning forward, with the hips and knees flexed. Usually, children experience pain with trunk extension.

The diagnosis is usually suggested by the history and physical examination findings and confirmed with radiographs. At times, advanced imaging is necessary. For example, single-photon emission tomography scan is useful when the diagnosis is suspected but radiographs are normal. A CT scan is useful for gaining a better assessment of bony detail, and an MRI is useful when neurologic symptoms are present.

In the absence of symptoms, spondylolysis or spondylolisthesis with less than a 50% listhesis requires no treatment. If a child has significant low back pain, then activity modification, physical therapy, and a brace may be used in an effort to ameliorate the symptoms. For those with recalcitrant pain or pain associated with slips of greater than 50%, surgical stabilization may be necessary. In cases of spondylolysis, in an otherwise normal spine, an attempt can be made to perform a pars interarticularis repair, treating the defect like a fracture and avoiding a formal spinal fusion. Theoretically, this is a motion-preserving procedure. For those with spondylolisthesis, particularly listhesis greater than 50%, surgical stabilization is most often accomplished by an instrumented spinal fusion. Whether the listhesis should be reduced or whether the surgery is performed anteriorly, posteriorly, or by a combined approach remains a topic of considerable debate.

### Infections of the Spine

*Pyogenic spondylitis* is a term used to describe both diskitis and vertebral osteomyelitis. Both entities may represent different spectrums of the same process. This is a common cause of back pain in children younger than 8 years. Because the disc is relatively avascular, the infection most likely starts in the vertebral end plates and then involves the disc. With time, the vertebral body becomes involved. These children may present with abdominal pain, back pain, limp, or refusal to walk. The differential diagnosis is broad. At times, these children may seem ill. Typically, they try to avoid flexion of the spine and have a very hard time picking objects up off the floor. They typically flex through their knees and avoid flexing the trunk. Inflammatory markers such as C-reactive protein and erythrocyte sedimentation rate are commonly elevated.

The radiograph of a child with pyogenic spondylitis reveals disc space narrowing and end-plate irregularities. Magnetic resonance imaging further delineates the extent of disease and reveals any abscesses (Figure 333-12, Figure 333-13).

**Figure 333-11** Spondylolysis of L4.

**Figure 333-12** Lateral radiograph of a child with L3-4 diskitis.

Treatment is generally nonsurgical. Infectious disease consultation may be appropriate. Antibiotic treatment targeted for *Staphylococcus aureus* is usually curative. An orthosis may be used to treat pain. For those who do not respond, an image-guided percutaneous biopsy can be performed.

It is important to keep atypical infections in mind when evaluating children with spinal infections. Tuberculosis of the spine (Pott disease) typically affects the vertebral body to a greater extent and can spread subligamentously (beneath the anterior longitudinal ligament). As with pyogenic spondylitis, treatment is generally medical in nature.

**Chapter 334****SPORTS MUSCULOSKELETAL INJURIES***Nirupama Kannikeswaran, MBBS; Srinivasan Suresh, MD, MBA*

Sport injuries result from acute trauma or repetitive stress associated with athletic activities. Thirty to 35 million children ages 5 to 18 years participate in organized sports in the United States. Many athletes now train in sports year round and frequently play several sports at a time. Organized sports account for only approximately one-third of sports injuries, with the remainder occurring in physical education classes and recreational sports. A study based on the national emergency medicine data set (2008) estimated that approximately 432,609 emergency department (ED) visits were made by 13- to 19-year-old children who experienced sports-related injuries, with total charges close to \$447.4 million and a mean total per-visit charge of \$1,205. The most frequently occurring injuries were superficial injury or contusion ( $n = 118,250$  ED visits); sprains and strains ( $n = 105,476$ ); fracture of the upper limb ( $n = 63,151$ ); open wounds of the head, neck, and trunk ( $n = 46,176$ ); and intracranial injury ( $n = 30,726$ ). The incidence of traumatic brain injury in children ages 5 to 14 years increased by 40% from 498.8 to 888.7 per 100,000 visits from 2001 to 2010.

Wrestling and football have the highest significant injury rates per participant in high school, followed by softball, gymnastics, track and field, and soccer. Tennis and swimming produce the fewest injuries. Frequency of injury, however, is not always the best measure of a sport's risk. The trampoline, for example, accounts for a disproportionately large number of injuries that cause paralysis. Although younger athletes appear to be at greater risk for injury because of lack of experience, injury rates are actually higher in older athletes because of increased speed, strength, size, and competitive motivation. Indeed, injury rates are higher in older high school students than among junior high and younger participants.

This chapter discusses some issues regarding sports participation such as drug use, overuse syndromes, and acute trauma-related injuries. It also discusses the common problem of anterior knee pain in young athletes. Sports medicine is a discipline in itself. This chapter can serve only as an introduction to some of the more common problems. Sports medicine texts should be consulted for more information on treatment and exercises for rehabilitation.

Most sports injuries are predictable and often preventable. Estimates suggest that nearly two thirds of all injuries might be reduced by improvements in conditioning, equipment, compliance with rules, coaching and supervision, rehabilitation of existing injuries, and efforts to prevent reinjury.

Many schools use certified athletic trainers for the prevention of and rehabilitation from sports injuries. These programs should be encouraged and supported. Inexperienced coaches with high expectations

of young athletes and a poor understanding of training may contribute to injury.

Participation in organized sports provides an opportunity for young people to increase their physical activity and develop physical and social skills. However, when the demands and expectations of organized sports exceed the maturation and readiness of the participant, the positive aspects of participation can be negated. The nature of parental or adult involvement can also influence the degree to which participation in organized sports is a positive experience for children of all ages. The American Academy of Pediatrics (AAP) offers recommendations on how primary care physicians can help determine a child's readiness to participate, how risks can be minimized, and how child-oriented goals can be maximized. The AAP also provides information for primary care physicians on sports participation for children and adolescents with medical conditions.

**DRUG USE IN ATHLETES**

Athletes frequently use drugs and nutritional supplements that they believe will give them a competitive advantage or improve their strength or appearance. The AAP and the American College of Sports Medicine have issued policy statements condemning the use of these supplements.

Despite this warning, use of drugs and stimulants is exceedingly common. Anabolic steroid use has been reported to be as high as 5% to 11% among high school boys and 2.5% among high school girls.

Anabolic steroid use is most common among football players and track participants. Clues to excessive use include jaundice, increased acne, behavioral changes (aggressiveness, irritability, marked mood swings), gynecomastia, and testicular atrophy. Women may develop hirsutism and deepening of voice. Liver enzymes may be elevated, and lipid profile may be adversely affected. Although controversy exists, anabolic steroids do appear to increase muscle mass and decrease catabolism of muscle in some situations. Anabolic steroid withdrawal may cause side effects such as mood changes, irritability, hot flashes, nausea, myalgia, malaise, tachycardia, and hypertension. Little information is available on long-term effects.

The Anabolic Steroids Control Act of 1990 made most anabolic steroids schedule-3 controlled substances (abuse of the drug may lead to moderate or low physical dependence or high psychological dependence). Illicit distribution is a felony. However, androstenedione, often mentioned in the media as a drug used by major league baseball players is still available without a prescription. Unlike most androgen supplements, creatine supplements can be obtained legally at many gyms and health food stores. Though they are not banned in professional sports or in the Olympic games, some supplements are found to contain small doses of stimulants that may cause athletes to test positive for banned substances. Creatine is converted to phosphocreatine in muscle with the help of the enzyme creatine kinase. Phosphocreatine is believed to serve as a reservoir for the depletion of the high-energy phosphate adenosine triphosphate

(ATP). The idea behind the supplements is that excess phosphocreatine will lead to a higher rate of ATP re-synthesis during exertion and delay the fatigue that results from activities requiring short bursts of high-intensity muscle contraction. Little evidence exists that creatine is helpful in endurance sports. Some athletes argue that it helps them train more vigorously by reducing the time to recover from exertion.

Creatine supplements appear to increase serum creatinine levels, which is not an indication of renal dysfunction but a reflection of an increased creatinine load. Long-term effects of such supplements are unknown. The American College of Sports Medicine recommends against creatine supplementation in athletes younger than 18 years old.

## INJURIES TO BONE AND SOFT TISSUES

Injuries related to sports participation fall into the general categories of overuse syndromes that develop over time and acute traumatic injuries.

### Overuse Syndromes

Overuse injuries are characterized by injury to bone, cartilage, or soft tissue caused by repetitive submaximal physical stress. In contrast to an acute fracture or soft-tissue injury, the tissue breakdown in overuse injuries occurs gradually. This phenomenon of hard- and soft-tissue breakdown is a normal, daily occurrence. The body continually remodels these tissues so that they recuperate fully. Overuse injuries happen when the chronic repetitive stress overwhelms the normal reparative processes without sufficient recovery time.

In young athletes, the frequency with which these problems occur has grown tremendously over the last several decades. Box 334-1 lists factors that contribute to overuse injuries in young athletes.

An increasing proportion of youths are becoming involved in competitive sports. More young athletes are training harder and longer than before as competition intensifies. Many athletes now train year round for participation in a sport, whereas others participate in several sports each year, even playing several sports at a time. Time off is not usually considered a

priority. Inexperienced coaches may have unrealistic expectations of young athletes. All these factors contribute to the growing number of training errors that often underlie these conditions.

Prevention of overuse syndromes involves the education of young athletes, their parents, their coaches, and the entire health care team, from trainers to physicians. Understanding these principles is crucial to returning an athlete to sports successfully after experiencing one of these overuse conditions. Failure to change the underlying problem often simply results in reinjury.

### Stress Fracture

Stress fracture of bone is conceptually the simplest overuse syndrome of the musculoskeletal system. When there is an imbalance between bone resorption and formation, repetitive loading of the bone leads to microfracture that eventually progresses to a stress fracture. Stress fracture commonly occurs with long-distance running. Hard running surfaces, poor footwear, overtraining, and female athlete triad (amenorrhea, disordered eating, and osteoporosis) are some of the risk factors associated with stress fractures. Nearly 50% of stress fractures occur in the tibia. Other commonly reported sites are the metatarsals, fibula, navicular bone, and lumbar spine. The usual presenting symptom is pain during or soon after activity and eventually progresses to pain at rest. Plain radiographs have a low sensitivity for diagnosing stress fractures, and can be normal for up to the first 3 weeks with symptoms. A bone scan has a high sensitivity, but low specificity. Magnetic resonance imaging (MRI) is the diagnostic modality of choice. Avoiding painful activities is crucial until healing occurs. The athlete can typically return to the sport after being pain free for 1 month.

### Metaphyseal and Diaphyseal Stress Injuries

The athlete may experience gradual onset of symptoms of metaphyseal and diaphyseal stress injuries. Eventually, pain may preclude running. In some circumstances, the weakened bone may fail completely and result in a complete or displaced fracture. Although most of these injuries occur in later adolescence (ages 16–19 years), some do occur at younger ages. Typically, the distribution of male and female patients is equal. Metaphyseal and diaphyseal stress fractures in young athletes most commonly involve the fibula, metatarsals, tibia, femur, and ulna, but virtually any bone can be affected. Stress fractures of the metatarsals (typically the second or third) and the distal fibula rarely have complications other than pain and temporary disability. Fractures of the tibia, humerus, and forearm rarely displace, but they have the potential to do so. Stress fractures of the hip are rare but have the highest potential for morbidity; displaced femoral neck fractures can disrupt the blood supply to the femoral head and lead to avascular necrosis and arthritis.

A bone scan may detect an early stress fracture of the metaphysis or diaphysis (see Table 334-1). The bone scan findings, however, must be correlated to the clinical symptoms. As many as 50% of adolescents

#### BOX 334-1 Factors Contributing to Overuse Injuries in Young Athletes

- Training errors
- Increased recreational time
- Increased intensity and duration of competition
- Increasing standards of competition
- Inadequate preseason conditioning
- Suboptimal facilities and equipment
- Overly enthusiastic coaches and parents
- Participation in multiple sports
- Lengthy seasons

with stress fractures will show multiple areas of stress response on bone scan, many of which do not correlate to areas of symptoms. For stress fractures, MRI may be the most sensitive study.

Most diaphyseal and metaphyseal stress fractures are managed by rest. Crutches are often necessary. Occasionally, casts and immobilization are needed. Healing time ranges from 4 to 12 weeks. A well-designed plan of alternative training, gradual resumption of participation in sports, and monitoring for recurrent symptoms is necessary. Stress fractures occasionally require surgical intervention.

### Apophyseal Conditions Osgood-Schlatter Disease

In 1903, Osgood and Schlatter separately described a disorder of the proximal tibial apophysis that commonly affects young athletes but may affect other active youngsters who are not involved in formal, organized sports. The tubercle of the proximal tibia is the insertion site of the patellar tendon. The quadriceps is the strongest muscle group in the body, and the tensions it generates through the patellar tendon are enormous. Stresses applied at the interface between the tendon and the apophysis create a disruption of the normal transition from the ossified and unossified tubercle into the tendon. This condition commonly occurs with impact and decelerating activities such as running, jumping, and cutting. Patients are typically 10 to 15 years of age at the time of onset of this disorder.

Boys are more commonly affected than girls; however, female gymnasts are particularly prone to this problem. Approximately 15% of teenage boys and 10% of teenage girls have complained of pain at their tibial tubercle at some point. Bilaterality is high, though its reported incidence varies considerably. The average youngster with symptomatic Osgood-Schlatter disease has significant pain, tenderness, and swelling of the tubercle on the presenting side and usually has some degree of findings on the contralateral side as well. Many of these patients have a history of heel pain compatible with Sever disease (calcaneal apophysitis). As many as 20% to 30% have siblings who also have had apophysitis. Signs and symptoms of intra-articular problems of the knee joint itself are absent. A lateral radiograph of the knee can help confirm the diagnosis by showing irregularity of the tibial tubercle and rule

out a tumor or infection, which can mimic Osgood-Schlatter disease.

In most patients, Osgood-Schlatter disease will run its course with time. Symptoms can last for 1 to 4 years. In approximately 3% of patients, a persistent ossicle will form that can remain symptomatic and may ultimately require surgical excision. Fracture of the tibial tubercle has been reported in patients with Osgood-Schlatter disease; its incidence is not known, but it appears to be low. Thus, remaining active in sports is possible.

The symptoms are often relieved with topical application of an ice pack to the area, intermittent use of oral nonsteroidal anti-inflammatory drugs (NSAIDs), application of a compression band over the area, activity modifications as indicated by the symptoms, and hamstring stretching. Casts are not routinely used because immobilization may weaken ligament insertions. However, brief periods of rigid immobilization may be necessary for acute exacerbations.

### Sinding-Larsen-Johansson Disease

Sinding-Larsen-Johansson (SLJ) disease affects the inferior pole of the patella and typically occurs as a result of the same stresses that lead to Osgood-Schlatter disease. Although an apophysis is not present at the inferior pole of the patella, a transition of the patellar ligament fibers occurs as they join the bone. In response to chronic repetitive stresses, the patellar periosteum can create a bony reaction, which is a classic finding of SLJ disease. Repetitive, eccentric, and decelerative loading of the extensor mechanism of the knee such as running, jumping, and kicking sports exacerbate symptoms.

Affected children are typically 10 to 13 years of age. They complain of well-localized pain at the inferior pole of the patella. As with patients with Osgood-Schlatter disease, they have no signs or symptoms of internal derangement of the knee joint itself. On physical examination, they exhibit point tenderness at the inferior edge of the patella, and typically have no other abnormal findings. A lateral radiograph of the knee may demonstrate irregular ossification at the inferior pole of the patella. Some physicians mistake this finding for a fracture.

Pain in the same area without radiographic change is often caused by patellar tendonitis or jumper's knee. This phase is an early stage of SLJ disease. With

**Table 334-1**      **Parts of the Growth Plate of a Long Bone**

NAME	ROOT ORIGIN	DEFINITION
Physis	—	Specialized area of growth cartilage occurring at both ends of major long bones or at 1 end of the smaller tubular bones, such as metatarsals and phalanges
Epiphysis	Epi- (on)	Secondary ossification center interposed between the physis and joint articulation
Metaphysis	Meta- (next to)	Flared transition from the primary spongiosa of the physis to the dense tubular bone of the diaphysis
Diaphysis	Dia- (in between)	Dense cortical and tubular bone comprising the shaft
Apophysis	Apo- (arising from)	Specialized growth cartilage area to accommodate insertion of a major tendon

advanced skeletal maturity, the periosteal reaction is usually not seen.

This entity is self-limited and typically lasts 3 to 12 months. Similar to Osgood-Schlatter disease, treatment with ice, NSAIDs, and activity modification may be helpful. Immobilization and surgery are rarely necessary. Rupture of the patellar tendon or a sleeve fracture (avulsion of the inferior pole of the patella with attached cartilage) is not a well-recognized complication of this disorder. In general, athletes may participate in sports as tolerated.

### **Calcaneal Apophysitis**

Calcaneal apophysitis, or Sever disease, occurs at the apophyseal insertion of the Achilles tendon into the calcaneus. The patient is typically 9 to 14 years of age, with a substantial peak occurring at 10 and 11 years of age. Most (60%–80%) cases are bilateral. This is usually seen in impact sports that involve running and in sports in which cleats are worn.

Athletes may complain of heel, ankle, or foot pain. On physical examination, however, the discomfort is typically well localized at the region of the calcaneal apophysis. It is typically medial or posterior, although occasionally the tenderness may be on the lateral side. Rarely does the tenderness occur distal near the origin of the plantar fascia. No swelling, warmth, or limitation of motion should be present. Occasionally, because of concurrent tendonitis, some tenderness can occur along the course of the Achilles tendon itself. Pain is reproducible with medial and lateral compression of the heel (“the squeeze test”). No classic radiographic change of calcaneal apophysitis is seen. Significant irregularity of the ossifying calcaneal apophysis is a normal finding at this age and should not be confused with evidence of a fracture.

Radiographs of the heels can be obtained to rule out other osseous processes, such as tumor or infection. In bilateral cases, radiographs are only necessary if some atypical component of the history and physical examination exists, which raises concern about some other diagnosis.

Treatment focuses primarily on symptom management. This condition almost always resolves with time, and complications are extremely rare. Shoe inserts that provide padding beneath the heel can be helpful. The material must be resilient enough so that it does not collapse. Typically, a 3/8-inch silicone or felt pad works best. Ice, NSAIDs, and activity modification may be indicated based on severity of symptoms. Casts or controlled ankle motion walkers (removable rigid walking splint) are occasionally necessary for severe cases. Surgery is not indicated.

**LITTLE LEAGUE ELBOW.** Little League elbow is seen in young throwing athletes, especially pitchers, and is caused by traction of the medial structures of the elbow during the acceleration phase of pitching. The term is used to describe a group of injuries of the elbow, including apophysitis and fragmentation of the medial epicondyle, and osteochondritis dissecans of the radial head and capitellum. Patients usually present with medial elbow pain and have localized tenderness of the medial epicondyle. These athletes

should refrain from throwing until symptoms resolve. Specific therapy includes muscle strengthening and pitch training. Activity modification and adherence to league regulations that limit the number of pitches are beneficial.

## **Repetitive Physeal Injuries**

### **Little League Shoulder**

Little League shoulder, or physiolysis of the proximal humerus, is a widening of the proximal humeral physeal plate. It occurs almost exclusively in Little League baseball players. It typically affects pitchers, but occasionally, players who do a lot of throwing from other positions can develop Little League shoulder. Usually the patient is a 12- to 15-year-old boy who complains of pain in the shoulder related to overhead throwing. The key consideration in the differential diagnosis is internal impingement, which presents in younger, overhead athletes. This refers to a constellation of conditions that include rotator cuff tears, labral tears, biceps tendonitis, anterior instability, and scapular dysfunction, which result from the performance of repetitive actions at the limits of arc of motion under extreme loading conditions. This results in pathologic changes at the point of contact of the humeral head with the undersurface of the rotator cuff in the gleno-humeral joint resulting in labral and rotator cuff injury. Many of the signs and symptoms are the same. Another differential diagnostic consideration is impending pathological fracture from a simple bone cyst in the upper humerus.

Radiographic widening of the proximal humeral physis on the affected side confirms the diagnosis of Little League shoulder. The essence of treatment is rest. Complications are uncommon. If the symptoms are minimal, then the young baseball player can often be allowed to bat and play in an infield position that involves minimal throwing. Clinical and radiographic resolution can take up to 6 months. A carefully planned resumption of pitching can then begin, but monitoring for recurrence of symptoms is necessary.

### **Physeal Widening of the Distal Radius**

Physeal stress injury of the distal radius occurs almost exclusively in young female gymnasts (“gymnast’s wrist”). These injuries usually cause progressive pain in the wrists. Most often the pain is bilateral, but it may be more prominent on 1 side. On physical examination, point tenderness is often present, and a prominence may be noted on the dorsum of the distal radial physis. Differential diagnoses include carpal laxity with dorsal wrist capsular impingement, posterior interosseous neuroma, and avascular necrosis of the lunate. Anteroposterior and lateral radiographs should demonstrate the physeal widening. Comparison films of the other side are almost always obtained, though both sides may be involved. Typically, some asymmetry is noted.

Premature closure of the distal radial physis has been described, resulting in relative overgrowth of the ulna at the wrist. This closure causes asymmetric loading of the carpal bones, which can lead to chronic wrist disability. The goal of treatment is resolution of symptoms and normalization of the radiographs,

which usually takes 3 months or longer. Once the athlete returns to gymnastics, clinical and radiographic monitoring are required.

### Epiphyseal Overuse Conditions

The best example of a repetitive stress-related injury of the epiphyses occurs at the capitellum (the lateral condyle of the distal humerus where it articulates with the radius). These injuries are typically classified as osteochondroses rather than stress fractures. In osteochondroses, a segment of epiphyseal bone and overlying articular cartilage becomes loose.

### Osteochondritis Dissecans of the Capitellum

Although the term *osteochondritis dissecans* implies an inflammatory process, there is no histologic evidence. Osteochondritis dissecans is clearly a repetitive stress phenomenon, and it occurs most commonly in baseball pitchers. As the ball is released during the pitching motion, a valgus movement occurs at the elbow. Tension occurs on the medial side of the elbow, and compressive forces are created across the radial capitellar articulation. The capitellum has an end-arterial blood supply, which may be partially responsible for its susceptibility to avascular necrosis from these chronic repetitive compression forces.

Any pitching style that releases the ball lateral to the body's midsagittal plane accentuates the valgus moment at the elbow. Therefore side-arm pitches and many curve-ball techniques can increase the compression loads across the lateral side of the elbow.

Patients typically experience aching pain in the lateral side of the elbow. With time, they can lose range of motion. Osteochondral fragments can displace acutely, resulting in a loose body sensation, a locked elbow, significant synovitis, and pain. Plain film radiographs often demonstrate a lesion of the capitellum. Either a sclerotic region or radiolucency may be present. Tangential views may be necessary to visualize the lesion. Occasionally, computed tomography scanning or MRI or both are helpful.

Unlike most overuse syndromes in young athletes, the sequelae of this condition are not always benign. Osteochondritis of the capitellum can result in permanent arthrosis of the elbow joint.

Junior baseball programs typically have rules limiting the frequency and duration that youngsters can pitch. Typically, this limit is 3 innings per game and up to 6 innings per week. Young athletes, parents, and coaches need to be educated about this condition so that excessive pitching does not occur at other times. The American Sports Medicine Institute has published recommendations to prevent injuries in youth baseball players.

Cases of osteochondritis dissecans of the capitellum occasionally heal with prolonged rest. However, surgery is indicated for locked elbow, symptomatic loose bodies, and persistent pain and limitation of movements after a period of nonoperative treatment.

### Overuse Syndrome of Soft Tissues

#### Tendonitis

Tendonitis is seen with less frequency in young athletes compared with their adult counterparts because the apophysis (site of attachment of the tendon to

bone) is weaker than the tendon itself and more likely to get injured. Tendonitis is divided into 3 stages based on the progression of the disease. These stages are (1) from inflammation of the paratenon (the fatty or synovial tissue between a tendon and its sheath), (2) through inflammation of the tendon itself, and (3) into degenerative change of the tendon that ultimately results in rupture. Typically in young athletes, only the earliest inflammatory stage is seen.

The most common tendonitis in young athletes is that of the Achilles tendon, seen usually in dancers, gymnasts, and figure skaters. Symptoms are typically located 2 to 6 cm above the insertion of the Achilles tendon into the calcaneus. Some lack of flexibility in the gastrocnemius muscle group may be found on physical examination. Other sites include the rotator cuff in throwing athletes and swimmers, and the ilio-psoas in dancers.

The diagnosis is typically made clinically. Radiographs and MRIs are rarely indicated. The treatment in young athletes is entirely nonoperative. If analysis of lower extremity mechanics during gait suggests a hyperpronation pattern, then custom foot orthoses can help control this hyperpronation. Ice, stretching, and NSAIDs are also used. Training modifications and heel lifts can be helpful as well. Immobilization is rarely necessary.

#### Internal Impingement

The rotator cuff is a convergence of the tendons of the subscapularis, supraspinatus, infraspinatus, and teres minor muscles. These tendons extend laterally from the scapula over the humeral head. Together, they function to help stabilize the humeral head in the glenoid fossa of the scapula. A particularly important function of the rotator cuff is preventing the upper humerus from impinging on the superior glenoid and undersurface of the rotator cuff. The supraspinatus muscle is most important for this function.

Many factors contribute to rotator cuff tendonitis. In young athletes, inherent laxity of the glenohumeral capsule (ligament complex) is likely to be a significant factor. Sporting activities that stress the shoulder joint with the arm extended overhead are particularly prone to precipitate symptoms. Some typical activities include overhead throwing in baseball, swimming, tennis serves, and gymnastics. Once a shoulder becomes irritated, a reflex arc inhibits the firing of the rotator cuff muscles. This precipitates further dysfunction of the shoulder muscle and leads to impingement of the humeral head beneath the acromion. With time, a well-established bursitis and tendonitis develop. Typically, the patient complains of pain with overhead activities. In many instances, the athlete will complain of the arm becoming heavy or tired or feeling dead. Full-thickness rotator cuff tears are almost never seen in children younger than 18 years.

The neck and shoulder should be thoroughly examined, assessing for range-of-motion limitation, muscle atrophy, and focal tenderness in the subacromion region, both anteriorly and laterally. Tenderness may occur along the course of the biceps tendon as well. Bringing the shoulder fully overhead may produce pain; this finding is referred to as a *positive impingement test*.

**Table 334-2**     **Severity Grading of Sprains**

GRADE	DESCRIPTION	CLINICAL PRESENTATION	TYPICAL RECUPERATION TIME
I (mild)	Stretching of the ligament with minimal microscopic injury	Mild swelling, limp	0–2 wk
II (minor)	Partial disruption of the ligament	Modest swelling, diffuse tenderness, difficulty bearing weight	1–4 wk
III (severe)	Complete disruption of the ligament	Extensive swelling and bleeding, instability, and disability	4–12 wk

The supraspinatus strength should be tested, and glenohumeral laxity should be assessed as well. Plain film radiographs are not diagnostic of rotator cuff tendonitis but are often obtained to rule out other bony abnormalities. An MRI can be diagnostic for rotator cuff tendonitis but is often not necessary. The diagnosis can usually be made clinically.

### Acute Trauma

Acute injuries include sprains, muscle tears, and fractures. Sprains are injuries to ligaments, and they typically are graded from mild to severe (see Table 334-2).

The fundamental principles of treatment for many musculoskeletal injuries go by the acronym RICE (rest, ice, compression, and elevation). Rest is especially important for the first 24 to 72 hours after a significant injury. For lower-extremity injuries, crutches should be used to avoid bearing weight. Randomized studies have demonstrated that athletes can return to full activity faster if cryotherapy is begun immediately after the injury. Ice may be applied for 20 minutes every 2 to 4 waking hours. A wet cloth can be used between the ice and skin to decrease the chance of cold injury. Many trainers advise continuing the use of ice until the swelling disappears completely. Compression may be applied with an elastic bandage. The goal of elevation is to place the injured extremity above the level of the heart to aid in reducing edema.

### Ankle Sprains

Ankle sprains are the most common musculoskeletal injury in sports and account for 28% of all sports-related injuries. Approximately 97% involve the lateral ankle ligaments. Rarely, the syndesmosis (high ankle sprain) and medial ligaments are involved. The typical mechanism of injury involves inversion and external rotation of the foot, which results in a sequential tearing of the anterior talofibular ligament, calcaneal fibular ligament, and finally, the posterior talofibular ligament.

The presence of bony tenderness should be determined, particularly over the distal fibula, the anterolateral tibia, the medial malleolus, the base of the fifth metatarsal, or the proximal fibula. In the skeletally immature athlete, the bone is usually weaker than the ligaments; thus lateral ankle injuries often result in physeal fractures of the distal fibula. Sometimes, separating focal tenderness over the physis from diffuse tenderness of the lateral ankle ligaments can initially be difficult. Percussing with the tip of the finger can

often separate tenderness at the proximal physis from tenderness around the ligaments.

Stress tests such as anterior drawer and talar tilt can be performed to confirm the diagnosis and grade injury severity. Anterior drawer test is performed by using a brisk motion to pull the heel forward with the ankle relaxed in 10-degree plantar flexion, and stabilizing the distal lower leg with the nondominant hand. The test result is positive if more anterior displacement is noted compared with the uninjured side. Talar tilt test assesses the calcaneal fibular ligament. It is performed using a brisk motion to invert the calcaneus and the talus on the fibula, with the ankle in neutral or slight dorsiflexion and stabilizing the distal lower leg with the nondominant hand. The test result is considered positive if there is more inversion compared with the uninjured ankle.

The distal fibular physis is weaker than the surrounding ligament; therefore, all skeletally immature athletes need radiographs of the ankle to rule out fibular fracture. As simple as the injury may sound, the treatment options for ankle sprains are complicated. Treatment modalities vary widely and are chosen based on the severity of the injury (see Table 334-2), the demands of the athlete, and the experience of the treating health care team.

If the injury does not appear severe, then RICE principles can be applied and the ankle periodically reevaluated. At reevaluation, if the pain is minimal and the ankle is stable, the athlete should then be observed in functional tasks such as running, cutting, and twisting. If these tasks are performed well without significant pain, then the individual may return to competition. Ideally, the ankle should be taped or splinted to lessen the risk of reinjury, and a preventive physical therapy program should be considered.

For ankle sprains of moderate grade, many other options come into play. For the less-serious athlete, an expectant approach can be used, including crutches, elastic bandage wrap, and gradual progression of weight bearing, with the athlete returning to sports only after symptoms resolve. Occasionally a cast or controlled ankle motion walker is helpful. For the serious athlete with moderate-grade sprains, referral to a physical therapist is often helpful. Range of motion is begun early, and strengthening is emphasized. As the ankle becomes comfortable, a proprioception training phase of rehabilitation begins. In all cases, functional criteria for return to sports, prevention of reinjury, and reassessment of progress are key components.

Severe-grade sprains should be managed by someone with advanced skills in dealing with musculoskeletal problems. A period of immobilization to reduce bleeding and swelling is often helpful. Assessment for chronic laxity and tarsal coalitions should be made. The risk of reinjury after an initial ankle sprain is 5 times higher and 20% to 40% of athletes experience chronic ankle instability. Return to sports averages 8 days for grade I, 15 days for grade II, and 28 days for grade III lateral ankle sprains.

Persistent anterolateral ankle pain can occur after even mild ankle sprains. In many instances, this ankle pain is caused by an area of fibrosis or synovial hypertrophy in the anterior lateral corner of the joint. The differential diagnosis should include chondral and osteochondral injuries at the dome of the talus, chronic laxity of the ankle or subtalar joints (or both), and tarsal coalition. If symptoms persist, then referral to an orthopedist or sports medicine specialist is indicated.

### **Collateral Ligament Injuries of the Knee**

Injuries to the medial and lateral collateral ligaments occur rarely in skeletally immature individuals, because ligaments are stronger than the growth plates. Physeal injuries should always be suspected in children with open growth plates. The collateral ligaments of the knee originate from the epiphyses of the femur and insert into the epiphyses of the tibia and fibula, with 1 exception. The distal portion of the superficial medial collateral ligament inserts over a broad area of the proximal tibial metaphysis. The mechanism is a valgus stress and/or external rotation of the tibia on a fixed foot, and often occurs in contact sports. The player reports sharp medial knee pain, immediate swelling, and inability to bear weight. Physical examination reveals severe limitation of range of motion.

Plain film radiographs may not be diagnostic. Stress radiographs or an MRI are usually needed to make this diagnosis. Concurrent injury to the cruciate ligaments, menisci, and articular surfaces need to be considered as well.

Most collateral ligament injuries heal satisfactorily. Initially, the principles of RICE are used. Depending on the severity of the injury, the knee is mobilized as the swelling and tenderness diminish. As range of motion returns, strength should be assessed. A physical therapist or athletic trainer can be helpful in designing an adequate rehabilitation program. For moderate- and severe-grade sprains, the use of a dual, upright, hinged, functional knee orthosis should be considered.

### **Anterior Cruciate Ligament Injuries**

As adolescents become skeletally mature, the incidence of anterior cruciate ligament (ACL) injuries rises rapidly. While ACL injuries can occur from direct contact of the lower extremity of an athlete with another player or an object, about 70% of these injuries occur without any contact mechanism (noncontact). Such noncontact ACL injuries occur with evasive maneuvers that involve some form of deceleration, change of direction, or landing. Four factors: hormonal, anatomic, environmental, and neuromuscular,

particularly predispose female athletes to noncontact ACL injuries.

Overall incidence of ACL injuries is about 1 in 100 high school-aged athletes, with girls 2 to 8 times more likely to sustain these injuries. The increased incidence in girls is thought to be the result of the effect of estrogen on ACL laxity, genu valgum, shape of the intercondylar notch, hyperextensible knees, and poor neuromuscular control of knee motion during athletic tasks such as landing and cutting. These injuries are commonly seen in sports that involve cutting and twisting such as soccer, basketball, gymnastics, and football.

In classic cases, athletes describe an acute pop and pain in the knee after a rotational injury on a fixed foot. They often fall to the ground and experience moderate to severe pain. The knee typically swells within the first few hours because of the development of a hemarthrosis with significant limitation in range of movements. Occasionally the tenderness is not marked, and athletes will attempt to return to their sporting competition, only to discover that the knee is not stable, which may worsen the injury. A high index of suspicion should be maintained for ACL injury and it must be ruled out before the young athlete with a knee injury returns to practice or competition.

The most sensitive physical examination component is the Lachman examination, which is performed with the patient lying supine; the knee is gently flexed to approximately 30 degrees. The patient must be able to relax the quadriceps and hamstrings enough to allow the examiner to attempt to slide the proximal tibia anteriorly. Although the amount of movement of the tibia has some importance, the key factor is the endpoint. If the test is negative (ie, the ligament is intact), then a distinct endpoint or cessation of forward movement should be felt. This endpoint should feel similar to holding the 2 ends of a short piece of rope and quickly pulling the ends apart until the movement suddenly stops.

This test may however be falsely negative soon after the injury when the knee is painful and swollen. The size of the patient's leg, the ability of the patient to relax, and the size of the examiner's hands are factors that contribute to successful performance of the test. If doubt exists, then the knee should be reevaluated later or the patient referred to an orthopedist.

Radiography should be performed in a skeletally immature athlete to rule out a tibial eminence fracture that can mimic an ACL injury. Radiographs may also reveal a "Segond fracture" (avulsion fracture of the lateral aspect of proximal tibia) which is pathognomonic of an intra-articular injury. Arthroscopy or MRI is often required for a definitive diagnosis of an ACL injury.

Initial treatment for an ACL injury consists of RICE and bearing weight as tolerated. Aspiration of the joint may be helpful in relieving pain in athletes with a large hemarthrosis. A comprehensive rehabilitation program including weight-bearing and range of motion exercises should be initiated early. The rehabilitation program should include an assessment of and remedy for biomechanical predisposition to ACL injury. Specific exercises that encourage balance, coordination, and reaction will help to sharpen the

responses in the surrounding structures, thus minimizing the effect of the lost ligament. Left without the stability of the ACL, most knees in young, active adolescents eventually become symptomatically unstable, and reinjury will occur. For the very young athlete, a brace, physical therapy, and activity modification is probably the best approach to managing ACL injuries. In older and less-active patients, nonoperative management of these injuries plays a role; however, most ACL injuries in young athletes should be reconstructed. In contrast to the collateral ligaments of the knee, the healing potential of the ACL is limited because of its susceptible vascular supply. As a result, most injuries to the ACL do not heal well, and primary surgical repairs (as opposed to reconstructive surgery) are not effective.

Return to sports varies from 6 to 12 weeks for those treated nonoperatively to 6 to 8 months for those who undergo surgical reconstruction.

### **Meniscal Tears**

The meniscal cartilages have several important functions within the knee joint. These functions include providing mechanical shock absorption between the weight-bearing articular cartilages of the femur and tibia, enhancing the distribution of synovial fluid, which provides nourishment to the superficial portion of the articular cartilage, and enhancing the stability of the articulation between the tibia and femur. Loss of the meniscal cartilages has little detectable effect on the knee joint initially. However, over the ensuing decades, particularly after 20 years, the rate of degenerative joint disease rises significantly. As a result, all reasonable efforts should be made to protect, preserve, and repair menisci of younger patients.

In youths 10 years of age and younger, most meniscal tears are related to discoid menisci. These menisci are congenitally abnormal, and are almost always on the lateral side of the joint. Discoid menisci are thicker than normal menisci, less mobile, and much more prone to tear.

A discoid variant, the Wrisberg type, has thick margins and is usually not attached to the capsule posteriorly. These patients exhibit a classic finding of a snapping knee. As the knee actively extends, it suddenly shifts and pops as the thick, mobile discoid meniscus shifts between the weight-bearing surfaces of the tibia and femur.

For patients older than 10 years, the incidence of tearing of normal menisci rises. Most commonly, this tearing occurs in association with significant ligament injury, such as a tear of the ACL. Rarely do normal menisci in teenagers tear without a substantial injury. As a result, meniscal tears are not typically at the top of the list of differential diagnoses of a young athlete with gradual onset of nonspecific knee pain. Meniscal tears usually occur when the knee is twisted during weight bearing. The player reports a popping sensation, a feeling of the knee “giving out,” and “locking of the knee” with inability to fully extend the knee.

Meniscal tears are assessed with the McMurray and Apley compression tests. The former is performed with the patient supine, by flexing the knee and applying valgus stress on the lateral aspect of the knee. Then the

knee is flexed and extended while alternately internally and externally rotating the tibia. A ‘click’ indicates a positive test result. The Apley test is performed with the patient prone and the knee flexed to 90 degrees. Pressure is applied to the heel while the tibia is rotated. Presence of pain with this maneuver indicates a positive test.

If a meniscal tear is suspected, then an MRI or referral to an orthopedic surgeon is indicated. Some studies suggest that MRI may not be as sensitive and specific for meniscal tears in children as in adults, and hence, judicious use of MRI is recommended.

The pattern and location of the tear determine whether the meniscus may heal on its own or will require arthroscopic partial removal or repair. The principles of treatment are to preserve as much of a normal functioning rim of meniscal cartilage as possible while alleviating the mechanical snapping that ultimately leads to degenerative changes of the articular surfaces. Symptomatic discoid lateral menisci require surgical intervention.

### **Quadriceps Contusion**

Minor contusions of the quadriceps muscle are common events in contact sports such as football, soccer, and lacrosse. However, significant hematomas can develop within the quadriceps, which can be quite disabling. More extensive hematomas have a propensity to rebleed. Myositis ossificans traumatica (heterotopic ossification of the muscle) may develop, which can also be disabling.

The key finding for separating minor hematomas from major ones is limitation of knee flexion when tested 12 to 24 hours after injury (mild >90 degrees; moderate, 45–90 degrees; severe, <45 degrees). Occasionally, differentiating a large quadriceps hematoma from a malignant tumor of the thigh becomes challenging, such as Ewing sarcoma and osteosarcoma, both of which have a propensity to occur in teenagers and which may bleed internally themselves.

Initial treatment of quadriceps hematoma involves RICE and crutches. As pain and swelling diminish, active knee flexion exercises are begun. Full return of motion is the minimal requirement for return to contact sports, at which time a padded guard should be used. Monitoring for reinjury is essential. Return to sports averages 13 days for mild contusions, 19 days for moderate contusions, and 21 days for severe contusions.

### **Avulsion Fractures of the Pelvis**

Six major apophyses are present on each side of the pelvis. These apophyses include the iliac crest, the anterior-superior iliac spine, the anterior-inferior iliac spine, the lesser trochanter, the greater trochanter, and the ischial apophysis. Each of these areas is prone to develop an apophysitis, and, except for the greater trochanter, avulsion fractures also are fairly common.

An avulsion fracture typically causes acute onset of pain during a sudden athletic motion. Examples include an explosive start for a sprint, an extreme pike maneuver (hips flexed and knees extended) in gymnastics, or a combination twisting movement and direct blow to the iliac crest. A complete history will

sometimes reveal mild antecedent symptoms consistent with a preexisting apophysitis.

Findings include focal tenderness to palpation over the affected apophysis and pain with resisted strength testing of the corresponding muscle insertion or origin. The diagnosis can often be confirmed with plain film radiography. Special oblique views and occasionally a computed tomographic scan or an MRI are helpful.

Most of these avulsions do not cause significant displacement; almost all heal with time and rest. Typically, crutches and rest are suggested for the first few weeks. Stretching may inhibit healing and should be avoided until the site is pain free. Complete healing typically takes 6 weeks to several months. The athlete should gradually return to activity and be monitored for recurrence of symptoms.

### Muscle Strains

Injuries to muscle tendon units almost always occur at the musculotendinous junction. These are caused by a sudden forceful change in the length of the muscle-tendon unit, resulting in a stretch or tear of the muscle fibers. Similar to sprains, muscle tendon injuries vary in severity from mild to severe, depending on the degree of injury to the muscle and range of motion. Mild injuries heal fairly rapidly, whereas severe strains can lead to large areas of scar tissue that are prone to reinjury.

The diagnosis of muscle strain has several pitfalls. Muscle strains are not as common in young athletes as they are in older athletes. The diagnosis of a strain is too often applied to a musculoskeletal malady for which the true diagnosis is not obvious to the examiner. Particularly around the hip and thigh area, the examiner should be careful not to miss a slipped capital femoral epiphysis, an avulsion fracture, an infection, or a tumor as causes of pain.

The most common muscle strain in teenage athletes is of the hamstring. This strain causes pain at the junction of the middle and distal thirds of the posterior thigh. More proximal hamstring tenderness should raise suspicion of an occult injury to the ischial apophysis.

The treatment principles for hamstring strain initially involve RICE and crutches. Reduction of tenderness can take days to weeks, depending on the initial severity of the injury. Once comfortable, a gradual stretching and strengthening program is initiated. The athlete can return to activities as tolerated and be monitored for recurrent symptoms. Reinjury is likely in 12% to 31% of hamstring strains. Return to play ranges from 2 to 3 days for mild strains to 3 to 12 weeks for severe strains.

### Dislocations

The most common dislocations of young athletes include patella, shoulder (glenohumeral joint), elbow, and fingers. With severe trauma, dislocations and fracture dislocations can occur in virtually any joint, and musculoskeletal specialists generally manage these injuries.

**PATELLAR DISLOCATION.** A common musculoskeletal dislocation in young athletes involves the patella. Patellar dislocation should not be labeled as knee dislocation, which denotes displacement of the

articulation between the tibia and femur. The latter is a high-energy injury and has a high associated morbidity including, occasionally, loss of limb. By contrast, patellar dislocation is often the result of a trivial injury. Many individuals are predisposed to dislocation of the patella as a result of genetic variability in their knee extensor mechanism. Variations leading to easy dislocation include a shallow sulcus in the distal femur, lateral translation of the insertion of the patellar tendon into the tibia, relative underdevelopment of the vastus medialis muscle, and tightness of the lateral retinaculum.

The incidence is estimated at approximately 43 children per 100,000 and is similar in both sexes. Almost all patellae dislocate to the lateral side. The history of injury can vary from a minor twisting episode to a significant direct blow to the knee. Occasionally the athlete will report having seen a medial prominence, but this is typically because the medial femoral condyle is exposed by the displaced patella.

A patellar apprehension test, wherein the athlete expresses fear that the patella may dislocate as the examiner applies gentle laterally directed pressure, is almost always positive. Ninety percent of patellar dislocations resolve spontaneously. Manipulative reduction can often be achieved relatively easily. Procedural sedation and gentle extension of the knee will result in the reduction of the laterally located patella.

Unless the patellar dislocation or subluxation is a trivial event that incites little pain in the joint, radiographs should be obtained to assess for osteochondral fragments. These loose pieces typically arise from the lateral femoral condyle or the patella.

After a significant patellar dislocation, the knee is immobilized, and the principles of RICE are used. As the pain and swelling subside, a rehabilitation program is initiated that emphasizes strengthening of the quadriceps muscles, particularly the vastus medialis. The hamstrings are stretched and a lower extremity rehabilitation program is undertaken. A patellar-stabilizing knee sleeve is used during the initial phases of return to activity.

Most patellar dislocations can be successfully managed with a single therapeutic program. Recurrent patellar instability, particularly in those with a familial history, may require reconstruction.

**SHOULDER DISLOCATION.** As with the patella, dislocations of the shoulder joint can occur from relatively minor trauma in predisposed individuals or as a result of major trauma in the average person. Approximately 90% of the dislocations are anterior. Posterior dislocations tend to occur with seizures or trauma. The most common mechanism of injury is a forceful abduction/external rotation with or without an associated fall. The patient typically holds the affected arm in a cradle position, and there is loss of shoulder contour.

Reduction can occur spontaneously; however, fixed dislocations can be difficult to reduce. These dislocations may require transportation to an emergency care facility. Reduction may require expertise, local anesthesia, sedation, and occasionally, general anesthesia. Unless the episode is minor, radiographs are generally obtained to confirm reduction and rule out an associated fracture.

Traditionally, shoulder dislocations have been treated with 3 weeks of immobilization, followed by a rigorous physical therapy program. The therapy should be directed at strengthening the rotator cuff muscles. The principle is to strengthen these dynamic stabilizers of the joint to help compensate for laxity of the shoulder joint capsule. Recurrent instability despite a therapy program is generally an indication for surgical stabilization.

### Anterior Knee Pain

The most common knee complaint of adolescents is that of anterior knee pain. This ubiquitous symptom can arise from a wide variety of disorders. In many cases, a specific diagnosis such as Osgood-Schlatter disease, SLJ disease, patellar tendonitis, or patellar instability can be made. In some instances, a degree of psychological overlay to the symptoms can be found, which can make management challenging.

Some of the more common causes of anterior knee pain have been discussed previously, and 2 additional entities—chondromalacia patella and patellofemoral pain syndrome—are discussed here. A wide variety of less common disorders not discussed in detail here can cause anterior knee pain. These disorders include quadriceps tendonitis, bipartite patella, osteochondritis dissecans of the femur or patella, iliotibial band tendonitis, popliteus tendonitis, and prepatellar bursitis. Osteomyelitis, septic arthritis, inflammatory arthritis, and tumors should always be kept in mind.

### Chondromalacia Patella

The term *chondromalacia patella* refers to softening of the articular surface of the patella, which can occur in mild to severe grades, ranging from edema of the cartilage to complete ulceration of the articular surface. This term had previously been misapplied to virtually any case of anterior knee pain. The diagnosis should be reserved for specific instances of symptomatic articular change of the surface of the patella.

In mild cases, the pain from chondromalacia patella will abate with intermittent use of NSAIDs, a quadriceps-strengthening program, and judicious activity modification. Although a therapy program can be helpful, the patient must have a clear understanding that the goal is to reduce symptoms. Completely eliminating symptoms may not be possible. Occasionally, surgical intervention to alter the patella's articular surface is indicated.

### Patellofemoral Pain Syndrome

The typical patient with patellofemoral pain syndrome is a teenage girl older than 12 years who complains of a diffuse pain over the anterior surface of her knee. Predisposing biomechanical factors, including femoral anteversion, external tibial torsion, pronating gait, and increased valgus alignment at the knees, may be present. In some cases, the syndrome may result from training errors. Sudden increase in mileage, running on hard surfaces, poor preseason conditioning, and inadequate footwear may be contributing factors. Although the cause of this problem is not clear, investigators believe that an abnormality of the tracking of the patella is responsible. Abnormal stresses in the

patellofemoral articulation or the surrounding soft tissues are probably responsible. Typically the long-term history of this presentation is benign, though the symptoms can be troublesome.

The typical onset is insidious and without a specific history of trauma. Usually, no signs of erythema, warmth, induration, or effusion is noted. Occasionally, patients describe the knee having become slightly puffy. Typically, mechanical complaints of catching or locking are absent. Popping may be present, and is usually painful. On physical examination, tenderness is often present along the medial and lateral sides of the patellofemoral articulation. Mild discomfort may be felt over the anterior portion of the joint line, but typically no tenderness occurs over the middle or posterior portion of the tibial femoral articulation. The joint is stable with full range of motion and no crepitation. The knee is stable. Plain film radiographs are usually negative. Further diagnostic evaluation is not indicated.

The most important role of the physician in this case is to rule out other serious or more specifically treatable disorders. For patients with significant flexible flat feet, foot orthoses such as arch supports may reduce pronation at the foot and thereby diminish torsional stresses applied at the knee. Stretching and strengthening the quadriceps muscles often reduces anterior knee pain. The principles are to strengthen the vastus medialis and improve patellar tracking. Occasionally, taping or supportive knee sleeves will provide relief. The intermittent and judicious use of NSAIDs may help as well. In some cases, adjustment of expectations and activities is necessary. Psychological concerns need to be considered as well. In refractory cases, referral to a musculoskeletal specialist may become appropriate.

## WINTER SPORTS INJURIES

Millions of people ski, snowboard, and sled each year in the United States. These cold weather activities result in many injuries each year. Various winter sports have distinct injury characteristics (see Table 334-3).

In general, children are more likely to experience upper extremity injuries, and lower extremity injuries are more frequent in adolescents and adults. Children younger than 10 years incur more fractures and

**Table 334-3**

### Injuries Associated With Winter Sports

SPORT	INJURY
Downhill snow skiing	Knee contusions, anterior cruciate ligament sprains, spiral fracture of tibia
Cross-country snow skiing	Medial collateral ligament sprain, acute ankle inversion strain, acromioclavicular joint separation, skier's toe, hypothermia
Snowboarding	Wrist, ankle, and knee injuries
Snowmobiling	Multisystem trauma with head injury
Sledding	Head and face, extremity, abdominal injuries

catastrophic injuries (head injuries) with individual recreational activities than they do with organized winter sports.

## CONCUSSION

The American Academy of Neurology defines concussion as a clinical syndrome of disturbance of brain function typically affecting memory and orientation, which may involve loss of consciousness caused by an impact or jolt to the head. About 1.4 million ED visits are made annually for traumatic brain injury, of which 75% to 90% are the result of concussions. However, this is likely to be underreported because the majority of athletes who sustain a mild traumatic brain injury do not seek medical care or attention. Among high school sports, football and ice hockey have the highest rate of concussion, followed by soccer, wrestling, basketball, field hockey, baseball, softball, and volleyball. The concussion rate is higher among men than women for all sports combined because of higher participation in sports by men. The age of the athlete or level of competition does not affect the rate of concussion. Use of head gear has been shown to have a protective effect against concussion.

The disturbance of brain function in concussion is secondary to changes in brain metabolism rather than structural damage as seen in severe brain injuries. Symptoms of concussion can manifest soon after injury or may be delayed for several hours. Signs and symptoms of concussion typically fall into 4 categories:

1. Physical: Headache, nausea, vomiting, ataxia, visual problems, photophobia and phonophobia, numbness/tingling, dazed, or stunned
2. Cognitive: Feeling slowed down and mentally “foggy,” difficulty concentrating, memory disturbances, confusion about recent events, slow response to questions
3. Emotional: Irritability, sadness, nervousness
4. Sleep: Drowsiness, sleeping more or less than usual, trouble falling asleep

Symptoms of concussion generally last for 72 hours and most of the symptoms resolve within 7 to 10 days. Recovery may be prolonged in some children and adolescents who have persistent concussive symptoms (see section on postconcussive syndrome). Athletes who exhibit worsening of symptoms such as persistent or worsening headache, persistent vomiting, altered mental status, irritability, and focal neurologic signs should be referred to the ED for evaluation.

Medical evaluation is recommended and mandated before participation in organized sports. The central goal of such preparticipation evaluation is prevention of concussion and prompt recognition and reporting of concussive injuries. It is to be reiterated that loss of consciousness is not the only symptom of an athlete having suffered a concussion. The history elicited should include number of previous concussions, severity of concussions, and time of recovery from previous concussions. In an injured athlete, after ensuring that airway breathing and circulation are adequate, acute management includes an assessment

of severity of concussion. Although a number of tools are available for this assessment, the Standardized Assessment of Concussion is well-validated, can be performed at the sidelines in 5 minutes, and has normative data for high school athletes.

Pediatric athletes need help from their parents and coaches to monitor their recovery from a concussion. Adequate sleep and limited physical and cognitive exertion have been shown to facilitate quicker recovery. Symptomatic students may require accommodations with school work until their cognitive functioning improves.

Return to play after a concussion has been the subject of much study and controversy, but most experts agree that an athlete can return to play when:

1. No signs or symptoms of any kind are apparent at rest or during exertion
2. Neurologic examination is normal
3. Neuroimaging, if performed, is unremarkable

## POSTCONCUSSIVE SYNDROME

Postconcussion syndrome (PCS) is defined as persistence of a cluster of cognitive, physical, sleep, and emotional problems beyond the usual period of recovery after a concussion. The presence of at least 3 symptoms 3 months after injury is required to meet the diagnostic criteria for PCS. PCS includes a number of disparate symptoms, such as headache, dizziness, fatigue, irritability, difficulty in concentration and performing mental tasks, memory impairment, insomnia, and reduced tolerance to stress, emotional excitement, or alcohol. Risk factors for persistent symptoms include adolescent age, loss of consciousness, posttraumatic amnesia, initial symptom of headache, high levels of initial symptoms, and a history of prior concussion. Symptomatic pharmacologic and rehabilitative interventions have been prescribed for PCS but the efficacy of such interventions is not known. Exercise, especially noncontact aerobic exercise, may be beneficial and have a positive impact on recovery from PCS provided the athlete avoids impact during the period of vulnerability for repeat injury.

### WHEN TO REFER

- When the diagnosis of the musculoskeletal injury is uncertain
- When injuries involve the growth plate in which future growth may be compromised
- When the patient is not responding to initial treatment
- When uncertainty exists in the safety of the young athlete to return to a competitive sports environment
- When an ACL tear or meniscal tear is suspected

### WHEN TO ADMIT

- Fractures requiring open reduction
- Fractures associated with neuro or vascular injury
- True knee dislocation

- Traumatic brain injury in conjunction with internal organ injuries

## Chapter 335 STOMATITIS

Linda S. Nield, MD

Stomatitis, or inflammation of the oral mucosa, is characterized by multiple ulcerations inside the mouth. Frequently painful, this condition may lead to decreased oral intake and dehydration.

### ETIOLOGY

Stomatitis can be a disease entity unto itself, such as recurrent aphthous stomatitis (RAS), or it may be a symptom of an underlying condition. Infection, trauma, irritant exposure, medical interventions, and systemic disorders are the major causes of oral inflammation.

#### Recurrent Aphthous Stomatitis

RAS is a benign condition characterized by painful oral ulcers that recur at irregular intervals. In otherwise healthy individuals, most cases are idiopathic. Although the exact cause of RAS is not known, stress, genetics, hormonal and immunologic influences, trauma, and smoking are suggested triggers for this common condition.

#### Infection

Viruses, bacteria, and fungi can inflame the oral mucosa. Some viral causes include herpes simplex, varicella-zoster, various subtypes of coxsackievirus, rubeola, Epstein-Barr virus, and HIV. Several coxsackieviruses cause an acute febrile illness associated with the development of lesions in the posterior oropharynx known as herpangina. Coxsackie A16 is the most common cause of hand-foot-mouth disease (HFMD), but other enteroviral subtypes have been implicated as causative agents.

*Borrelia vincentii* and *Fusobacterium dentium* are bacterial causes of oral inflammation known as *necrotizing ulcerative gingivitis*. Syphilis, gonorrhea, and tuberculosis can also lead to oral inflammation.

Fungal infections rarely occur in the immunocompetent child except for *Candida* spp. mucositis in the first several months of life. Histoplasmosis can develop in otherwise healthy children and produce mucosal ulceration along with other systemic manifestations.

#### Irritants

Exposure to a large array of external irritants can lead to stomatitis. The irritant may directly traumatize the mucosal surface (irritant contact stomatitis) or incite an allergic delayed-type hypersensitivity reaction (allergic contact stomatitis).

Trauma secondary to biting one's own mucosa or exposure to friction from dental appliances will cause irritant contact stomatitis. A rare condition known as *Riga-Fede disease* is characterized by the formation of ulcerative lesions of the lower lip, lingual frenulum, and ventral tongue secondary to repeated rubbing of the teeth against these mucosal surfaces. The age of onset of Riga-Fede disease is 6 to 8 months and coincides with the age of primary tooth eruption.

Exposure to excessive heat, cold, and acidic or basic substances can irritate the mouth. Smokeless tobacco is another mucosal irritant that has been found to lead to oral lesions in older school-aged children.

The most common causes of allergic contact stomatitis include preservatives and oral flavorings such as cinnamon, menthol, and peppermint. Metals, such as nickel found in dental instruments, may also elicit an oral allergic reaction.

### Iatrogenic Causes

Stomatitis may arise from medical interventions. Chemotherapy agents and radiation are the most notorious iatrogenic causes of mucosal breakdown. These treatments disrupt the mucosal barrier of the mouth, allowing ulceration, desquamation, and secondary infection by both acquired and endogenous flora. Infrequently, medications such as cyclooxygenase-2 inhibitors, non-steroidal antiinflammatory agents, and sertraline (an antidepressant) lead to oral dryness and the development of aphthous stomatitis. The misuse of commercial mouthwash with high alcohol content can also cause oral mucosal ulceration.

### SYSTEMIC DISORDERS

Although typically a benign, self-limited process, stomatitis may be one of the presenting symptoms of a serious, systemic illness such as Behçet syndrome, inflammatory bowel disease, gluten-sensitive enteropathy, diabetes mellitus, systemic lupus erythematosus, scleroderma, dermatomyositis, and granulomatosis with polyangiitis (Wegener). Stomatitis is also caused by periodic fever accompanied by aphthous stomatitis, pharyngitis, and (cervical) adenopathy (PFAPA syndrome), as well as cyclic neutropenia. Nutritional deficiencies of iron, vitamins B<sub>12</sub> and B<sub>6</sub>, folate, and zinc can also cause oral mucosal breakdown. Some dermatologic disorders associated with oral lesions include pemphigus, erythema multiforme, Stevens-Johnson syndrome, erosive lichen planus, and epidermolysis bullosa.

### EPIDEMIOLOGIC FACTORS

Because of the many diverse causes of stomatitis, a large number of children suffer from stomatitis at some time in childhood. RAS is the most common form of painful oral ulcers, and Kleinman and colleagues found that 37% of surveyed school-aged children reported a history of suffering from RAS. The peak age of onset of RAS is in the second decade of life, and bouts may recur throughout adulthood.

Viruses are the most common infectious cause of stomatitis. In the Kleinman study, 33% of the 5- to 17-year-old participants reported a history of recurrent herpes labialis. Herpangina and HFMD are also quite frequently experienced by young children. Outbreaks of acute stomatitis caused by herpangina are most likely to occur in the summer and early fall; HFMD is most likely to occur in the spring and summer. Bacteria and fungi infrequently cause stomatitis in otherwise healthy children, except for *Candida* spp. infection, in the first several months of life. The presence of syphilis and gonorrhea pharyngitis in a young child is rare and suggests sexual abuse and warrants a thorough child abuse investigation.

The number of children who suffer from stomatitis caused by irritants is not known; however, the use of orthodontic devices is quite prevalent, and oral flavorings and preservatives are ubiquitous in many commercial products. Oral inflammation secondary to medications is likely to occur only in the select group of children who use the offending agents.

Stomatitis as the only presenting feature of one of the systemic disorders does occur, but it is rare. About 15% of patients with aphthous ulcers and other symptoms will have a systemic disorder. PFAPA syndrome is a relatively newly described entity, with multiple case series reported in the medical literature.

### DIFFERENTIAL DIAGNOSIS

The differential diagnosis of stomatitis in children consists of the entities listed in Box 335-1.

### CLINICAL MANIFESTATIONS

Each of the conditions associated with stomatitis will display unique clinical features. The history of presentation of the oral lesions will provide the clues for the possible diagnosis. The time of year, the presence of local outbreaks, and the accompanying systemic symptoms should be noted. The physical examination will determine the location of the lesions and the presence of failure to thrive, fever, lymphadenopathy, organomegaly, and dermatologic and joint abnormalities.

#### BOX 335-1 Differential Diagnosis of Stomatitis

##### RAS: Infection

- Viruses: herpes simplex type 1, varicella-zoster, coxsackievirus and other enteroviruses, rubeola, Epstein-Barr virus, HIV
- Bacteria: *Borrelia vincentii*, *Fusobacterium dentium*, syphilis, gonorrhea, tuberculosis
- Fungi: *Candida*, *Histoplasmosis*

##### Irritant contact stomatitis

##### Allergic contact stomatitis

##### Iatrogenically induced stomatitis

##### Systemic disorders:

- Behçet syndrome
- Inflammatory bowel disease
- Celiac disease
- Diabetes mellitus
- Systemic lupus erythematosus
- Scleroderma
- Dermatomyositis
- Granulomatosis with polyangiitis (Wegener)
- PFAPA syndrome
- Cyclic neutropenia
- Nutritional deficiencies
- Dermatologic disorders

HIV, human immunodeficiency virus; PFAPA, periodic fever accompanied by aphthous stomatitis, pharyngitis, and (cervical) adenopathy; RAS, recurrent aphthous stomatitis.

The recurrence of 1 or more painful ulcers on the buccal, labial, and lingual surfaces, as well as on the floor of the mouth, characterizes RAS. The oral lesions will be the only physical examination finding. Three clinically distinct types of RAS have been described. Small, round craters, smaller than 5 mm in diameter and surrounded by an erythematous halo, typify the minor variety that heals in 1 to 2 weeks. The major variety may last 6 weeks and is characterized by lesions larger than 5 mm that often scar. The herpetiform variety is named as such not because herpesvirus is the etiologic agent but because of its herpes-like appearance of multiple, small clusters of pinpoint lesions that resolve in 1 week to 10 days. The child with RAS is otherwise healthy.

The primary infection with herpes simplex virus type 1 is associated with systemic signs and symptoms of fever, malaise, sore throat, and cervical adenopathy. Vesicles can develop anywhere on the oral mucosa but most typically in the anterior oropharynx on the lips, tongue, and buccal mucosa (Figure 335-1). The gingiva may be swollen and erythematous. The perioral area may also display vesicles and small ulcers that coalesce and continue to appear for the next week. Anorexia as a result of the oral pain may produce dehydration that is severe enough to warrant hospitalization. Children in the first few years of life are most likely to experience a primary infection, and recurrences vary in number. The recurrences are less severe than the initial bouts and are not usually associated with systemic symptoms. Spontaneous resolution occurs in 1 week to 10 days.

Herpangina is characterized by ulcers surrounded by erythematous halos located in the posterior oropharynx (Figure 335-2). Spontaneous resolution occurs in 3 to 5 days. In HFMD, along with lesions of the posterior oropharynx, blanching red macules or vesicles appear on the palms, soles, and buttocks. Erythematous halos may also surround the macules. Spontaneous resolution occurs within a week. Systemic

symptoms of fever, malaise, dysphagia, and anorexia accompany these coxsackievirus infections, which can lead to dehydration in children with either herpangina or HFMD.

The bacterial condition necrotizing ulcerative gingivitis is characterized by painful, erythematous, and friable gingiva. Foul breath accompanies the necrotic tissue that accumulates as a pseudomembrane over the gingival surface. Fever, malaise, anorexia, and dehydration may also be part of its clinical presentation.

Candidal mucositis produces white, curdlike patches on many of the surfaces of the oral mucosa. If scraped, then a white patch can be removed, unveiling ulceration at the base. Diaper dermatitis may also be present.

Contact stomatitis can present in 4 general ways: (1) red lesions with general mouth erythema, (2) white lesions and leukoplakia, (3) erosions and ulcerations, or (4) no obvious lesions accompanied by mouth pain and burning. Location of the lesions in close proximity to dental appliances, for example, will provide the clue that the etiology may be irritant contact stomatitis. The manifestation of stomatitis in the multitude of potential underlying multisystem diseases will vary depending on the diagnosis. Immunocompromised patients may experience more frequent and severe episodes of oral ulceration that take longer to resolve. The appearance of the individual aphthae in stomatitis secondary to a benign or self-limited condition may be indistinguishable from those associated with a serious underlying systemic disease. Therefore, the search for other symptoms and physical examination findings are important to help determine the appropriate etiology.

Ulcerations may occur in other body parts as well, such as in the genitals and gastrointestinal tract in Behçet syndrome. Gastrointestinal symptoms, fever, weight loss, joint and ocular abnormalities, and rash are some constitutional complaints that the child with an underlying disease may experience.

PFAPA syndrome is characterized by recurrent fevers every 4 to 6 weeks with onset in the first 6 years

**Figure 335-1** Herpes simplex stomatitis is a primary infection of the anterior oral mucous membranes. Tongue lesions also are common with primary herpes simplex virus infections.

**Figure 335-2** Herpangina (coxsackievirus) lesions on the posterior palate of a young male adult. Coxsackievirus lesions are usually found in the posterior aspect of the oropharynx and may progress rapidly to painful ulceration.

of life. Along with the symptoms described in its name, PFAPA syndrome may also cause general malaise, anorexia, headache, abdominal pain, and arthralgias that typically resolve within 1 week. The child has complete resolution of symptoms between the recurrences.

## LABORATORY EVALUATION

In most cases of stomatitis, laboratory evaluation is not helpful in the diagnosis or management of the patients. Monitoring serum electrolytes in patients with severe dehydration is prudent during the rehydration process. In the case of a child with stomatitis of uncertain etiology or oral lesions that persist for longer than 2 weeks, a further evaluation should be undertaken while the pain-relieving and hydrating measures continue. If frequently recurring or persistent oral aphthae are present, along with genital lesions or other systemic findings, an initial evaluation for an underlying cause may then include laboratory studies of complete blood count, erythrocyte sedimentation rate, and serum levels of iron, folate, vitamin B<sub>12</sub>, and zinc. Depending on the history, screening for anti-nuclear antibodies, HIV, and celiac disease may be necessary. Establishing the definitive diagnosis and appropriate treatment may require the expertise of an allergist-immunologist, rheumatologist, dermatologist, gastroenterologist, ophthalmologist, oral surgeon, or otolaryngologist, depending on the clinical scenario. A biopsy of an oral lesion may be needed, especially if the child chews tobacco and has a persistent, nonhealing ulcer.

## MANAGEMENT

### Uncomplicated Cases

Relieving pain and preventing dehydration are the goals of treatment for the child with RAS or stomatitis caused by an acute infectious process or for a child with contact stomatitis. By maximizing pain relief, the child will be able to remain hydrated and consume a soft diet. Systemic ibuprofen, acetaminophen, or opiates may help with the pain, but more relief may be obtained from the application of soothing, topical substances. In a cooperative child, the topical substances may be administered by allowing the child to swish and then spit or, alternatively, by painting the substance on the sores with a cotton-tipped swab. The many topical agents that have been studied minimally for safety and efficacy include saline rinses, diphenhydramine–aluminum hydroxide with magnesium hydroxide–viscous lidocaine compounded in various combinations, benzocaine, kaolin, and pectin. Most of these agents, if used too aggressively, can lead to overdose and adverse side effects. The topical anesthetic preparations, in particular, must be used cautiously because of the risk for aspiration, loss of protective airway reflexes, and systemic toxicity (such as methemoglobinemia) caused by absorption through the inflamed oral mucosa.

Antimicrobials are of limited value, except in the instance of necrotizing ulcerative gingivitis, in which case chlorhexidine mouth rinses and systemic antibiotics such as penicillin may be required. Oral acyclovir is of limited therapeutic benefit in the otherwise

healthy child with herpes stomatitis, and topical acyclovir is ineffective.

### Complicated Cases

An immunocompromised child or one with stomatitis secondary to cancer treatment should receive topical and systemic analgesics and be monitored for secondary infection. Topical sucralfate and capsaicin have been found to relieve the pain of chemotherapy or radiation-induced mucositis and are not routinely used for children with benign, self-limited conditions. However, these agents may be an option for an otherwise healthy child with persistent pain despite aggressive use of the standard medications. On a case-by-case basis, topical corticosteroids, local anesthetics, topical tacrolimus, and systemic medications (colchicine, dapsone, thalidomide) may be used to treat the oral symptoms in these complicated patients; however, these medications are not typically prescribed in general pediatric practice. PFAPA syndrome typically responds well to a short course of oral steroids (1–2 mg/kg/day for 5 days) if prescribed at the onset of symptoms.

## PREVENTION

Most causes of stomatitis cannot be prevented. In general, along with avoidance of tobacco products and any possible irritants, good oral hygiene should be promoted to reduce the risk for dental caries and gingivitis. Exposure to the proposed triggers for RAS should be lessened. Based on adult studies, continuous oral acyclovir is a therapeutic option for preventing recurrences in a child with frequent herpetic flares. Children with cancer may benefit from a preventive protocol that includes frequent plaque biofilm removal and teeth brushing, chlorhexidine or saline rinses, and nystatin.

### WHEN TO REFER

If the underlying cause of the stomatitis is uncertain, or if oral lesions persist for longer than 2 weeks, then referral to an oral surgeon or otolaryngologist should be considered for definitive diagnosis. Biopsy of a lesion may be necessary, especially for a child who uses smokeless tobacco.

A child with stomatitis plus multiple symptoms and abnormal physical examination findings may require the expertise of an allergist-immunologist, rheumatologist, dermatologist, gastroenterologist, or ophthalmologist to establish the definitive diagnosis and administer appropriate treatment.

## Chapter 336

## SUBSTANCE USE DISORDERS

Sarah Bagley, MD; Sharon Levy, MD, MPH

## INTRODUCTION

Most adolescents in the United States have used a substance—most commonly alcohol, marijuana, or tobacco—by the 12th grade. All psychoactive substance use during adolescence presents a health risk because even occasional use of substances is associated with a high risk of acute health consequences. For most adolescents who use substances with peers and without related problems or interference with domains of functioning, such as school and home life, the pediatrician can address their substance use in the medical home. Chapter 198, Substance Use: Initial Approach in Primary Care, describes the pediatrician's role in caring for children whose use does not rise to the level of a "disorder" and in identifying those who need the care of the substance abuse specialty system—many of whom have a substance use disorder (SUD).

Only about 10% of youth with SUDs receive care in the specialty system. By default, the primary care setting is often the site of initial care, requiring the pediatrician to be knowledgeable in the basics of treatment as well as referral.

This chapter introduces the new classification system for SUDs, summarizes the types of specialty services available for children with SUDs, provides information about commonly used substances, and recommends a role for pediatricians in supporting families and providing a medical home for children who receive substance abuse specialty care.

## CLASSIFICATION OF SUBSTANCE USE DISORDERS

In May 2013, the American Psychiatric Association *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (DSM-5) was released and included new terms and criteria. The terms "substance abuse" and "substance dependence" were replaced by *substance use disorder, mild, moderate, or severe*. The new diagnostic classification is based on the number of criteria that are met: 2 to 3 constitute a mild disorder, 4 to 5 moderate, and 6 or more severe. Meeting criteria for a mild or moderate SUD indicates that use is particularly hazardous or that an individual has begun to have problems associated with use. Meeting criteria for severe SUD, sometimes referred to as addiction, suggests that an individual has lost control over substance use, has cravings for use, and has a compulsion to use. Addiction is a chronic, neurologic condition associated with changes in the brain's reward center. Effective treatments, including medication and psychosocial support, are available. Addiction is treatable, but not curable, and so requires long-term treatment.

## SPECIALTY TREATMENT OF YOUTH WITH SUBSTANCE USE DISORDERS

A variety of evidence-based and evidence-informed psychosocial interventions are available for the treatment of SUDs in youth. Ideally, children referred for care in the substance use disorder specialty system have access to the safest and most effective treatments. Examples include cognitive behavioral therapy, community reinforcement therapy, and family therapy. Treatment should occur in adolescent settings and with licensed providers, although it is possible that adults may be treated in the same facility. Youth who use substances often have co-occurring mental health disorders; they require referral for mental health services, ideally delivered by a physician qualified to address both substance use and mental health needs. Many youth benefit from additional services such as individual counseling, school evaluation, neuropsychological evaluation, vocational services, or family counseling. The pediatrician may contact the local Bureau of Substance Abuse Services to find community resources.

Table 336-1 summarizes the types of referral options for substance abuse treatment, and Table 336-2 provides a description of the kinds of substance use treatment available.

## COMANAGEMENT OF YOUTH WITH SUBSTANCE USE DISORDERS

Referral of a youth to the SUD (or mental health) specialty system should not end the pediatrician's involvement with the youth. An SUD is a special health care need, and affected youths, like those with attention-deficit/hyperactivity disorder (ADHD) or asthma, continue to benefit from the services of a medical home in addition to subspecialty medical care. The pediatrician and specialist can reach agreement on respective roles in the youth's care and establish a mechanism for communicating progress. The pediatrician can support the youth by encouraging his or her positive view of treatment; monitoring progress in care; observing for co-occurring disorders; and coordinating care provided by parents, school, the medical home, and specialists. Resources available to help physicians in these roles are provided in Tools for Practice at the end of this chapter.

The pediatrician has an important role in supporting parents of youth with an SUD, as well as the youths themselves. The following are common issues that may arise and suggestions for how to manage them.

1. *Does a parent or other family member have an active SUD?* Explore this individual's readiness to seek and accept care. Advise parents that seeking an evaluation for their own substance use is excellent role modeling and emotionally supportive for their children. However, not all parents are receptive to such advice. The youth is the patient; his or her safety and well-being remain the priority. For his or her own well-being, suggest the youth attend a community-based support group like Alateen ([www.al-anon.alateen.org](http://www.al-anon.alateen.org)) and consider involving child protective services if the youth is at acute risk.

**Table 336-1** Referral Options for Substance Use Disorders

TYPE OF TREATMENT	CHARACTERISTICS
Outpatient treatment	<ul style="list-style-type: none"> <li>Includes community and school resources, 12-step groups, peer-support groups, and individual counseling and medication-assisted treatment in general medical settings</li> <li>May be used for youth who are motivated to change behaviors or whose caregivers and family feel that it will benefit them</li> </ul>
Partial or day hospital	<ul style="list-style-type: none"> <li>May also be used as a transition from more intensive treatment settings</li> <li>May be considered for youth who need more intensive structure and support to break the cycle of substance use</li> </ul>
Residential treatment	<ul style="list-style-type: none"> <li>May also be used as a transition from more intensive treatments</li> <li>Relatively long term (30–90 days)</li> <li>For youth who are unlikely to be able to stop drug or alcohol use if they remain in their home environment</li> </ul>
Inpatient treatment	<ul style="list-style-type: none"> <li>For those with a history of treatment failures in less restrictive settings</li> <li>Relatively short term (days to weeks)</li> <li>For youth in need of immediate stabilization because of safety concerns</li> <li>For those who have serious psychiatric disorders or symptoms (eg, suicidal, homicidal, psychotic, acutely dangerous behaviors) co-occurring with substance use disorders</li> </ul>

Derived from American Academy of Pediatrics Committee on Substance Abuse. Substance use screening, brief intervention, and referral to treatment for pediatricians. *Pediatrics*. 2011;128(5):e1330–e1340.

2. *Is the parent enabling the adolescent's use of substances?* Being the parent of a youth with an SUD can cause a great deal of strain on the family unit. Parents often struggle with setting appropriate limits around substance use. Pediatricians can guide parents in setting firm limits and consequences for use.
3. *Does the parent feel responsible?* Provide reassurance that the parent is not at fault. Adolescents commonly experiment with substances; as a result of a complex combination of risk factors, environment, and genetics, some will develop an SUD. Helping the parent realize that focusing on the present and supporting treatment for their child is the most important action he or she can take can help relieve the responsibility he or she may feel. In addition, some communities have groups for parents that can provide an important source of support.
4. *Does the parent understand that SUDs are brain diseases and not simply bad behavior?* Although SUDs and addiction are considered chronic medical conditions, stigma is associated with diagnosis. Explain SUDs in the framework of a medical model to help reduce the stigma and increase understanding.

## ACCURATE INFORMATION ABOUT SUBSTANCE USE

### Alcohol

Short- and long-term health effects are associated with alcohol use in adolescents. Common problems include unintentional accidents and injuries and unwanted sexual contact. "Blackouts" or periods of anterograde amnesia—episodes during which an individual walks and talks but has no subsequent memory—commonly occur with heavy drinking and place individuals at risk. Alcohol use during adolescence is associated with reduced hippocampus volume and

difficulties with memory and learning. Early initiation of alcohol use is also associated with developing an alcohol use disorder later in life. Adolescents with a family history of alcohol use disorders are at particularly high risk.

Adolescents who have experienced 1 or more negative consequences associated with alcohol use may be receptive to quitting or reducing alcohol use. Counseling should focus on the highest-risk behaviors, and all adolescents who agree to reduce alcohol use should be offered a follow-up appointment.

Symptoms of alcohol withdrawal in adolescents are rare, though adolescents who frequently binge drink may develop withdrawal syndromes of varying severity. The most common symptoms associated with alcohol withdrawal are nausea, vomiting, insomnia, autonomic hyperactivity, and confusion. Any adolescent with a history of daily heavy drinking should be observed for signs of withdrawal in an inpatient setting, because alcohol withdrawal can be life threatening.

### Marijuana

Marijuana refers to the dried leaves, flowers, stems, and seeds from the hemp plant, *Cannabis sativa*. The psychoactive component is delta-9-tetrahydrocannabinol, commonly known as THC. Marijuana is an addictive substance. Similar to other drugs with addictive potential such as heroin and nicotine, use of THC causes a release of dopamine in the brain's reward pathway in the nucleus accumbens, and long-term administration alters the limbic system in the brain. As with alcohol and other psychoactive substances, increased risk of addiction is associated with younger onset of use.

Since 2008, in the context of the national debate over marijuana policy, the perceived risk of harm of marijuana use has been decreasing and the rate of marijuana use by adolescents has been increasing.

**Table 336-2** Descriptions of Substance Use Treatment

<b>OUTPATIENT</b>	
Group therapy	A mainstay of substance abuse treatment for adolescents with SUDs. It is a particularly attractive option because it is cost-effective and takes advantage of the developmental preference for congregating with peers. However, group therapy has not been extensively evaluated as a therapeutic modality in this age group, and existing research has produced mixed results.
Family therapy	The best validated approach for treating adolescent substance abuse. A number of modalities have demonstrated effectiveness. Family counseling typically targets domains that figure prominently in the etiology of SUDs in adolescents: family conflict, communication, parental monitoring, discipline, child abuse/neglect, and parental SUDs.
Intensive outpatient program	Serves as an intermediate level of care for patients who have needs that are too complex for outpatient treatment but do not require inpatient services. These programs allow people to continue with their daily routine and practice newly acquired recovery skills both at home and at work. Intensive outpatient programs generally comprise a combination of supportive group therapy, educational groups, family therapy, individual therapy, relapse prevention and life skills, 12-step recovery, case management, and aftercare planning. The programs range from 2–3 hours/day, 2–5 days/week, and last 1–3 months. These programs are appealing because they provide a plethora of services in a relatively short period of time.
Partial hospital program	A short-term, comprehensive outpatient program in affiliation with a hospital that is designed to provide support and treatment for patients with SUDs. The services offered at these programs are more concentrated and intensive than regular outpatient treatment; they are structured throughout the entire day and offer medical monitoring in addition to individual and group therapy. Participants typically attend sessions for 7 or 8 hours/day, at least 5 days/week, for 1–3 weeks. As with intensive outpatient programs, patients return home in the evenings and have a chance to practice newly acquired recovery skills.
<b>INPATIENT/RESIDENTIAL</b>	
Detoxification	Refers to the medical management of symptoms of withdrawal. Medically supervised detoxification is indicated for any adolescent who is at risk of withdrawing from alcohol or benzodiazepines and might also be helpful for adolescents withdrawing from opioids, cocaine, or other substances. Detoxification may be an important first step but is not considered definitive treatment. Patients who are discharged from a detoxification program should then begin either an outpatient or residential substance abuse treatment program.
Acute residential treatment	A short-term (days to weeks) residential placement designed to stabilize patients in crisis, often before entering a longer-term residential treatment program. Acute residential treatment programs typically target adolescents with co-occurring mental health disorders.
Residential treatment	Highly structured live-in environments that provide therapy for those with severe substance abuse, mental illness, or behavioral problems that require 24-hour care. The goal of residential treatment is to promote the achievement and subsequent maintenance of long-term abstinence and equip each patient with both the social and coping skills necessary for a successful transition back into society. Residential programs are classified as short term (<30 days) or long term (≥30 days). Residential programs generally comprise individual and group-therapy sessions plus medical, psychological, clinical, nutritional, and educational components. Residential facilities aim to simulate real living environments with added structure and routine to prepare patients with the framework necessary for their lives to continue drug- and alcohol-free after completion of the program.
Therapeutic boarding school	Educational institutions that provide constant supervision for their students by a professional staff. These schools offer a highly structured environment with set times for all activities; smaller, more specialized classes; and social and emotional support. In addition to the regular services offered at traditional boarding schools, therapeutic schools also provide individual and group therapy for adolescents with mental health disorders or SUDs.

SUD, substance use disorder

Adapted from American Academy of Pediatrics Committee on Substance Abuse. Substance use screening, brief intervention, and referral to treatment for pediatricians. *Pediatrics*. 2011;128(5):e1330–1340.

Currently, 6.5% of high school seniors use marijuana daily. Unfortunately, the known harms of marijuana use in adolescents are often understated or completely neglected in policy debate. Heavy marijuana use in adolescence has been associated with increased mood, anxiety, and thought disorders and decreasing IQ scores over time. Imaging studies have demonstrated morphologic changes consistent with these findings. Physicians must be prepared to have conversations with adolescents about use as more states legalize marijuana for medical purposes and either decriminalize or legalize recreational use. Counseling should include a discussion of the known medical, psychological, and cognitive side effects and a clear statement that there is no known benefit to children or adolescents.

In addition to euphoria, marijuana use results in a loss of critical judgment, distortions in time perception, impairment of tracking (the ability to follow a moving object accurately), and poor performance on *divided-attention* tasks, such as driving. Other behavioral effects include impaired short-term memory, interference with learning, and difficulty with oral communication, all of which can affect school performance adversely. Occasionally, a pediatrician will encounter a child who has an acute adverse reaction to marijuana characterized by a toxic psychosis with depression or panic. Both the symptoms and the treatment of these reactions are similar to those for hallucinogen abuse. Prolonged (and possibly permanent) personality changes have been reported in long-term marijuana users. An example of a change is an amotivational syndrome, marked by lethargy and a lack of goal-directed activity. Physiologic effects do occur with marijuana use but are generally less acutely dangerous than those caused by other substances. Respiratory effects with prolonged exposure include bronchodilation with acute inhalation and subsequent chronic intermittent bronchoconstriction. Thus, adolescents who have asthma may experience either relief or exacerbation of symptoms. Allergic reactions to marijuana do occur and may cause asthmatic attacks. Furthermore, chronic marijuana use has been found to cause exercise-induced dyspnea and chronic cough that may be mistaken for new-onset asthma in an adolescent. Cardiovascular effects include both tachycardia and a transient low-grade elevation of systolic and diastolic blood pressure. Marijuana has been reported to have numerous effects on the endocrine system in boys and men who have histories of prolonged and frequent use, including depression of testosterone levels in the blood, diminished sperm counts, impaired sexual function, and gynecomastia. The associated clinical problems of impotence and infertility are expected to respond to abstinence from marijuana.

Marijuana withdrawal is more subtle than withdrawal from other substances and is therefore often overlooked. This is in part because marijuana's lipophilia ensures a slow physiologic taper even among individuals who quit "cold turkey." Marijuana produces pharmacologic tolerance after several days of regular use, and a clinical withdrawal syndrome begins within 24 to 48 hours of discontinuing the drug. Withdrawal

symptoms peak in intensity by the fourth day and gradually resolve by 10 to 14 days. The withdrawal symptoms from marijuana include anxiety, restlessness, and sleeplessness.

Use of synthetic cannabinoids, such as "spice" or "K-2," is common: 11% of 12th graders reported use in 2012 despite the US Drug Enforcement Agency's scheduling of the related chemicals in 2011. These substances are similar to THC and bind to the human CB1 receptor. They are synthesized chemically, dissolved in solvent, and sprayed on the leaves of a variety of plants so that they can be smoked like marijuana. As with other cannabinoids, binding at the CB1 receptor in the central nervous system results in euphoria, time distortion, intensification of sensory experiences, altered state of consciousness, impaired short-term memory, and increased reaction times. Also as with marijuana, use is associated with anxiety, hallucinations, paranoia, increased heart rate, and confusion, and can also be associated with myocardial ischemia and kidney failure.

### Other Drugs of Abuse

#### *Ecstasy/Molly*

The substance known as 3,4-methylenedioxymethamphetamine (MDMA, ecstasy, Molly) has recently gained attention because of a series of deaths in individuals who were not known to have SUDs. The resurgence of MDMA under the name Molly has been primarily among young adults; prevalence of past-year use of MDMA among 12th graders has decreased from its peak 9.2% in 2001 to 4% in 2013. Signs of MDMA toxicity include sympathetic overactivity, disturbed behavior, and hyperthermia. Serious complications such as delirium, seizures, and coma are more common when MDMA is used in combination with other substances, especially other stimulants. Rhabdomyolysis and acute renal failure have been reported with MDMA use by individuals who use the drug in the setting of prolonged physical activity such as all-night dance parties or "raves." All of these effects are potentiated by alcohol, benzodiazepines, and other drugs.

#### *Prescription Opioids and Heroin*

The use of opioids other than heroin by 12th graders peaked in 2004 at 9.5% and has continued to decrease to 7.1% in 2013. Use of heroin peaked in 2000 and has recently plateaued to 0.6% annual prevalence. Although not as common as alcohol and marijuana use, the risk of opioid misuse is high because of the high risk for addiction and associated complications, including fatal overdose and transition to injection drug use. For adolescents with suspected opioid use disorders, referral to specialty care—which may be either outpatient or residential—is key, because there is effective pharmacologic treatment available with buprenorphine-naloxone, a partial opioid agonist approved for adolescents 16 years and older. As with other conditions, adolescents with opioid use disorders should be treated in the least restrictive environment. Most adolescents with opioid use disorders are candidates for medication-assisted treatment in the outpatient setting. Few pediatricians have waived to prescribe buprenorphine to date, leaving a treatment gap.

Opioid withdrawal results in flu-like symptoms, including vomiting/diarrhea, myalgia, nasal congestion, and joint pain. These symptoms can be very unpleasant but generally are not life threatening in otherwise healthy adolescents. Medical detoxification programs can help to ease the discomfort associated with withdrawal, but should not be considered stand-alone treatment. Patients who have successfully completed detoxification should be referred to ongoing treatment.

### Prescription Stimulants

In adolescents with ADHD, stimulants can provide effective treatment; however amphetamines are also commonly misused by adolescents. An adolescent may misuse his or her own medication or take a friend's prescription. Misuse can be driven by a desire to get high and also to enhance academic achievement. Amphetamine use peaked at 10.9% in 12<sup>th</sup> graders in 2002. Since then, annual prevalence has fluctuated with an increase in 2013 to 8.7%. Children and adolescents with ADHD are at increased likelihood of developing an SUD; treatment for ADHD may lower this risk.

### SUMMARY

While substance use is common among adolescents and often does not rise to the level of a disorder, some adolescents do develop SUDs and require specialty treatment. These services may take place in outpatient, partial or day-hospital, residential, or inpatient settings and may incorporate a variety of evidence-based approaches, depending on the needs of the child. Pediatricians continue to play important roles in the care of children served by the SUD specialty system.

**Chapter 337****SUDDEN UNEXPECTED  
INFANT DEATH***Rachel Y. Moon, MD***DEFINITION AND DIAGNOSIS**

Sudden unexpected infant death (SUID); also sometimes referred to as sudden unexpected death in infancy, or SUDI) refers to all causes of death during infancy that occur suddenly and unexpectedly. Sudden infant death syndrome (SIDS), accidental injuries (including suffocation, strangulation, and entrapment), and undetermined causes of death comprise most SUID deaths; most of these deaths occur while the infant is sleeping. Undetermined deaths are those for which a cause of death cannot be definitively ascertained; for instance, the autopsy findings are consistent with SIDS, but the sleep circumstances suggest that suffocation is a possibility.

SIDS is defined as “the sudden death of an infant under 1 year of age, which remains unexplained after a thorough case investigation, including performance of a complete autopsy, examination of the death scene, and review of the clinical history.” It is a diagnosis of exclusion.

**INCIDENCE**

In the United States, SIDS and other SUIDs account for approximately 4,000 deaths annually; approximately half of these can be attributed to SIDS. Since 1992, when the American Academy of Pediatrics (AAP) recommended that infants be placed in a non-prone position for sleep as a strategy to reduce the risk for SIDS, the rate of prone sleeping has decreased from 70% to 13.5% in 2010, and the rate of SIDS has decreased from 1.2 deaths per 1,000 live births to .42 deaths per 1,000 live births in 2012. Similar decreases in SIDS have been experienced in other countries that have initiated similar educational campaigns. However, this decline in SIDS has occurred concurrently with an increase in the incidence of other causes of SUID, primarily accidental suffocation and strangulation in bed and undetermined causes of death. In fact, since 1984, infant deaths caused by accidental suffocation and strangulation in bed have quadrupled. Most of these deaths occur on either an adult bed or a couch. Some of the increase in the incidence of non-SIDS causes of SUID is likely because of a diagnostic shift. Largely because of more extensive and detailed death investigation protocols for infants, deaths that would have been attributed to SIDS a decade ago may now be ascribed to asphyxia or suffocation, or be undetermined by medical examiners and coroners. This is the case particularly when the infant is found in an unsafe sleep environment (adult bed, couch, cushioned chairs, soft bedding) or is bed sharing with an adult or another child. According to one examination of US mortality data, more than 90% of the drop in SIDS rates between 1999 and 2001 may be attributable

to a concurrent increase in the rates of non-SIDS causes of SUID.

Some racial disparities are seen in SIDS and SUID. In black infants, the rate of SIDS was 2 times that of white infants in 2012. Black infants are also 2.5 times and 2.8 times more likely than white infants to die from accidental suffocation and strangulation in bed or an undetermined cause of death, respectively. These disparities may be partially attributed to differences in sleep practices. African Americans are twice as likely to place their infants prone for sleep and to bed share with their infants; both of these practices are associated with increased risk for SIDS or other forms of SUID.

The occurrence of SIDS is rare in the first month of life, peaks between 2 and 3 months of age, and then decreases thereafter. Approximately 90% of SIDS deaths occur in the first 6 months of life. Similarly, deaths caused by accidental suffocation and strangulation in bed and undetermined deaths are more likely in young infants, with most occurring between 1 and 4 months of age.

Although SIDS is rare in infants during the first month of life, there is growing recognition of the increased vulnerability of apparently healthy newborn infants to SUID and apparent life-threatening events during the first week of life. This condition, referred to as sudden unexpected postnatal collapse (SUPC), is reported to occur in 2.6 to 38 of 100,000 live births. Infants appear to be most vulnerable during the first 12 to 24 hours of life. Contributing factors among infants without an underlying etiology include prone positioning of an infant on the mother's chest during skin-to-skin care, airway obstruction during breastfeeding, and maternal primiparity (inexperience) and/or maternal fatigue/sedation. (See Chapter 217, Apparent Life-Threatening Events, for additional discussion.)

**ETIOLOGY**

SIDS likely represents a variety of causes of death. However, the leading hypothesis regarding the etiology of SIDS is that certain infants, for reasons still unknown, have a maldevelopment or delay in maturation of the brainstem neural network that is responsible for arousal and the physiologic responses to life-threatening challenges during sleep. Postmortem examination of the brainstem of a series of infants who had died of SIDS, using quantitative techniques, have demonstrated deficits in serotonin receptors throughout the ventral medulla compared with age-matched controls who had died from some other well-defined cause. Authorities think that these brainstem regions are involved with arousal, chemosensitivity, respiratory drive, thermoregulation, and blood pressure responses. In addition, polymorphisms in the promoter region of serotonin transporter protein genes (5-HTT) have been associated with SIDS in several studies. When the physiologic stability of such infants becomes compromised during sleep, they may not arouse sufficiently to avoid the fatal noxious insult or condition. The rebreathing theory proposes that if the regular circulation of air around an infant's mouth

and nose becomes partially obstructed during sleep, exhaled CO<sub>2</sub> is more likely to be trapped around an infant's face. If the infant does not arouse and move to amend the situation, the resultant hypercarbia and hypoxia lead to SIDS. Investigators have argued that prone sleep position, soft sleeping surfaces, soft bedding, and covering of the head increase the likelihood of rebreathing.

## DIFFERENTIAL DIAGNOSIS

When an infant dies suddenly and unexpectedly, a full investigation, including complete autopsy, death scene investigation, and review of the clinical history, should be undertaken to determine cause of death. Illnesses that should be considered in the differential diagnosis include sepsis, pneumonia, myocarditis, cardiomyopathy, congenital heart defect, arrhythmia, prolonged QT syndrome, trauma (accidental or nonaccidental), suffocation, strangulation, entrapment, SIDS, adrenal hypoplasia, and inherited metabolic disorders such as fatty acid oxidation disorders.

Most SIDS cases have no evidence suggesting parental psychiatric disease or neglect of the infant. However, much media attention has been given to a few cases of Münchausen syndrome by proxy causing apparent life-threatening events and of multiple cases of SIDS within a family later determined to be multiple homicides. The proportion of SIDS deaths attributable to homicide is probably less than 10%. A family in which an infant has previously died of SIDS has a 2% to 6% risk for a second SIDS death.

Suffocation, either accidental or nonaccidental, is difficult to distinguish on autopsy from SIDS. Indeed, since 1999, some deaths that would previously have been classified as SIDS are now being classified as suffocation. Therefore, the death scene investigation has become a crucial component in the determination of cause of death, and the Centers for Disease Control and Prevention have introduced a standardized protocol for investigating all sudden and unexpected infant deaths. When an infant death occurs in an environment where the infant's respiratory efforts have been compromised, such as may be seen when the infant was sleeping with soft bedding (pillows, blankets) or on a soft surface (couches, armchairs, some adult beds), suffocation is more likely than SIDS to be considered as the cause of death. When there are factors in the death scene investigation and/or review of the infant's clinical history that make it difficult to declare a cause of death with a degree of certainty, the cause of death may be declared as undetermined.

## EPIDEMIOLOGIC CONSIDERATIONS

The following characteristics have consistently been identified as independent risk factors for SIDS and SUID: prone or side sleep position, sleeping on a soft surface, maternal smoking during pregnancy, overheating, late or no prenatal care, young maternal age, preterm birth or low birth weight (or both), male gender, and African American or American Indian/Alaska Native origin.

Prone or side sleep position can increase the risk for rebreathing, and the prone position places infants at high risk for SIDS/SUID. Sleeping prone may create

fatal levels of hypercarbia in infants with an underlying vulnerability, such as an arousal defect. The side sleep position is inherently unstable, and a large proportion of infants placed on the side will roll to prone, which confers an exceptionally high risk for SIDS. Secondary caregivers (grandparents, babysitters, pediatricians, relatives) are more likely to place infants prone, which also increases the risk for SIDS, particularly if the infant is unaccustomed to the prone position.

Soft bedding, such as pillows, quilts, comforters, and sheepskins, and soft sleep surfaces, such as waterbeds, sofas, and soft mattresses, increase the potential for rebreathing and significantly increase the risk for SIDS and suffocation, when either placed under the infant or loose in the infant's sleep area. Crib bumper pads also increase a baby's risk for suffocation, entrapment, and strangulation. A strong interaction has been found between prone sleep position and soft bedding surface; these 2 factors together increase the risk for SIDS 21-fold. In addition, soft and loose bedding have been associated with accidental suffocation deaths. Soft surfaces have also been implicated in infant deaths occurring on adult beds.

Aside from sleep position, smoke exposure is the largest contributing risk factor for SIDS. Maternal smoking during pregnancy is a major risk factor; postnatal exposure to tobacco smoke is a separate risk factor, although separating this variable from prenatal maternal smoking is difficult. There is a dose-dependent relationship between tobacco smoke exposure and SIDS risk.

An increased risk for SIDS has been associated with increased layers of clothing or blankets on the infant and warmer room temperatures. Head covering during sleep also increases SIDS risk. Infants who sleep prone are at higher risk for overheating than supine sleeping infants. It is yet unclear whether overheating and head covering are independent factors or merely a reflection of the use of more clothing, quilts, and other potentially asphyxiating objects in the sleeping environment during cold weather.

Infants born preterm or who are low birth weight are at increased risk for SIDS, and the risk increases with decreasing gestational age or birth weight. The increased risk cannot be explained by a greater likelihood of apnea of prematurity among preterm SIDS victims while they are in the hospital after birth. Whether other complications of prematurity can explain the increased risk is unclear. The association of sleep position and SIDS is equally strong for infants born preterm as for those born at term. Strategies designed to reduce risk in full-term infants should also be applied to infants born preterm after they are no longer in an intensive care setting.

Physiologic and behavioral studies demonstrate that bed sharing between an infant and adult facilitates breastfeeding and enhances maternal-infant bonding. However, bed sharing may increase the risk for rebreathing and exposure to tobacco smoke (a known risk factor for SIDS), and epidemiologic studies have shown that it can be hazardous. In addition, bed sharing increases the risk for accidental suffocation and entrapment. The risk for sudden unexpected death during bed sharing is particularly high when

multiple people share the bed, when the infant is younger than 11 weeks, and when bed sharing occurs for the whole night. The risk for death also increases substantially when the infant is placed on excessively soft surfaces, such as waterbeds, sofas, and armchairs; when soft bedding accessories such as pillows or comforters are used; or when the parent is overtired or has consumed alcohol and/or medications that alter arousal. Bed sharing is particularly hazardous when one or both parents are smokers or if the infant is younger than 11 weeks, regardless of smoke exposure. Room sharing without bed sharing is associated with a reduced risk for SIDS. Notably, breastfeeding in bed has not been shown to carry a risk if the baby is returned to the crib after the feeding. Because breastfeeding has many benefits, including a reduced risk for SIDS, parents should be encouraged to bring the infant into bed for breastfeeding and for bonding. However, the baby should be returned to the crib or bassinet when the parent is ready for sleep.

More recent studies have demonstrated that breastfeeding offers protection against SIDS. Possible protective mechanisms include lower arousal thresholds, decreased infections, and immune system benefits. Exclusive breastfeeding and breastfeeding for longer duration offer the most protection, but any breastfeeding is also more protective against SIDS than no breastfeeding.

Pacifiers, by a yet unidentified mechanism, seem to reduce the risk for SIDS when used at sleep time. Case-control studies demonstrate a strong protective effect. However, because early pacifier use may interfere with establishment of good breastfeeding practices, pacifiers should not be offered for the first few weeks of life to breastfed infants until breastfeeding has been well established. In addition, practices that promote breastfeeding should be encouraged in delivery hospitals, and continued breastfeeding support for the parents should be offered.

## RISK REDUCTION

For many years, apnea was thought to be the predecessor of SIDS, and home apnea monitors were used in an effort to prevent SIDS. However, although they may be useful in some infants who have had an apparent life-threatening event, no evidence has been found that home monitors are effective in reducing the risk for SIDS when no event has occurred in a particular infant.

SIDS and SUID risk reduction has centered on eliminating risk factors that have been shown epidemiologically to be associated with these deaths. The AAP has made the following recommendations for SIDS risk reduction:

- Infants should be placed in a supine position for every sleep. Side sleeping is not as safe as supine sleeping and is not advised.
- A firm sleep surface, such as a firm crib mattress covered by a well-fitted sheet, should be used.
- Soft materials or objects such as pillows, quilts, comforters, sheepskins, and stuffed toys should not be placed under or near the sleeping infant. Loose bedding, such as blankets and sheets, should be avoided.

- Smoking during pregnancy or in the infant's environment should be avoided.
- A separate but proximate sleeping environment is recommended; the infant should sleep in the same room, in a crib or bassinet, close to the parent's bed.
- Offering a pacifier at nap time and bedtime should be considered. The pacifier does not need to be reinserted after the infant falls asleep and should not be forced if the infant refuses it. Pacifiers with attached strings or elastic should not be used for sleeping infants. Introduction of the pacifier should be delayed in breastfeeding infants until 1 month of age to ensure that breastfeeding is fully established.
- Overheating and head covering during sleep should be avoided.
- Commercial devices marketed to reduce the risk for SIDS should not be used.
- Home monitors should not be used as a strategy to reduce the risk for SIDS.

## Supine Sleeping and Plagiocephaly

With the increased rate of supine sleeping, the incidence of plagiocephaly without synostosis has increased. Infants with plagiocephaly are more likely not to have had the head position altered when placed for sleep, more likely to spend little awake time in the prone position (tummy time) and less likely to have been held in the upright position while awake. Development of positional plagiocephaly can be avoided by altering the supine head position during sleep; encouraging upright cuddle time; avoiding excessive time in car seats, infant carriers, and bouncers, all of which place pressure on the occiput; and encouraging tummy time when the infant is awake and observed. Awake tummy time will also enhance upper-body motor development. For more information on plagiocephaly, see Chapter 316, Positional Deformational Plagiocephaly.

## Supine Sleeping and Gastroesophageal Reflux

A perception exists that sleeping supine may increase the risk for gastroesophageal reflux, choking, and aspiration, and this is a common reason for parents and physicians to place infants prone for sleep. However, evidence indicates that infants who vomit are at greater risk for choking when they are prone. Indeed, the incidence of aspiration or complaints of vomiting has not increased with increased supine sleeping. Infants with gastroesophageal reflux should be placed for sleep in the supine position, with the rare exception of infants for whom the risk for death from gastroesophageal reflux is greater than the risk for SIDS, specifically infants with upper airway disorders for whom airway protective mechanisms are impaired. Elevating the head of the infant's crib while the infant is supine is not effective in reducing gastroesophageal reflux and may result in the infant sliding to the foot of the crib into a position that may compromise respirations; therefore, it is not recommended.

## MANAGEMENT AND SUPPORT

The loss of an infant to SIDS or SUID is devastating for the family, friends, and physicians. If there is lack of certainty as to how the infant died, this can add an additional and difficult element to the grief process.

The physician can play an active role by ensuring that an autopsy is performed in all cases of sudden unexpected death, discussing the results of the autopsy with the parents, and providing emotional support to the entire family, including age-appropriate support for surviving siblings. The family should be directed to local counseling and support groups.

## Chapter 338

## TOBACCO AND NICOTINE USE

Susanne E. Tanski, MD, MPH

### PREVALENCE OF TOBACCO AND NICOTINE USE

Tobacco use remains the leading cause of preventable morbidity and mortality in the United States. Cigarette

smoking, the most common form of tobacco use among US adults, leads to more than 480,000 premature deaths annually and has led to the premature death of more than 20 million people since 1964. Combusted tobacco products (including cigarettes, cigars, cigarillos, hookahs (waterpipe), bidi, kretek, pipes, and roll-your-own) clearly have more substantial health risks than noncombusted products, leading to deaths from cancers, cardiovascular diseases, stroke, diabetes mellitus, and respiratory diseases such as asthma, emphysema, and chronic obstructive pulmonary disease. Noncombusted products such as smokeless tobacco (dip, chew) and snus are not without harm, however, leading to dental issues as well as death from head and neck cancers. While the prevalence of cigarette smoking among US adults reached a low of 17.8% in 2013, 25.2% of adults reported current use (in the past 30 days) of any tobacco product. This reflects an increase in noncigarette products such as cigars and electronic cigarettes (e-cigarettes). Among youth, current use of any tobacco product by high school students in 2014 was 24.6%, which was very similar to the rate in 2013 (22.9%). Although cigarette use among high school students declined from 12.7% in 2013 to 9.2% in 2014, the prevalence of e-cigarette and hookah use increased significantly. From 2011 to 2014, current e-cigarette use among high school students increased from 1.5% to 13.4%, and hookah use from 4.1% to 9.4%. Figure 338-1 plots historic US adult cigarette use in the context of major health events.

Although flavors other than menthol are prohibited in cigarettes, such restrictions are not applied to other tobacco products. Approximately 70% of current high school tobacco users report using flavored products. There are substantial disparities in tobacco use between groups based on socioeconomic status, education, race/ethnicity, region of the country, and other demographics—men; those with lower educational attainment; those who live in poverty; those who identify as lesbian, gay, bisexual, and transgender; and Native American/Alaskan Natives have higher tobacco use. No form of tobacco use is safe, particularly for youth. Tobacco has been marketed extensively to attract users, and cigarettes in particular have been very carefully engineered to deliver nicotine quickly and efficiently to the brain to reinforce addiction. Cigarettes deliver a chemical cocktail of some 7,000 compounds that lead to disease and death, but it is the nicotine and its chemical relatives that lead to their ongoing use.

### HEALTH EFFECTS AND ADDICTION POTENTIAL OF NICOTINE

Nicotine is a psychoactive drug well known for its high level of toxicity, as well as the ease with which dependence occurs. Nicotine has complex pharmacodynamics: at low doses, it acts as a neurostimulant in the reward pathways, stimulating memory and alertness, improving mood, and decreasing appetite. At high doses, nicotine can cause nausea, vomiting, abdominal pain, headache, dizziness, and seizures; in very high doses, nicotine can be lethal. There are receptors for nicotine throughout the body, allowing

**Figure 338-1** Adult per capita cigarette consumption and major smoking and health events, United States, 1900–2012. (Adapted from *Fifty years of change 1964–2014*. In: US Department of Health and Human Services. *The Health Consequences of Smoking: 50 Years of Progress. A Report of the Surgeon General*. Atlanta, GA: US Department of Health and Human Services, Centers for Disease Control and Prevention, National Center for Chronic Disease Prevention and Health Promotion, Office on Smoking and Health; 2014.)

nicotine to have broad physiologic effects including suspected effects on the immune system. Repeated exposure to nicotine leads to tolerance, which results in higher nicotine needs to avoid withdrawal. Insufficient nicotine in someone who is dependent leads to craving and withdrawal symptoms of irritability, anxiety, restlessness, difficulty concentrating, and anhedonia/depression. The addictive potential of nicotine products is known to vary by the delivery of the nicotine: faster delivery, more rapid rate of absorption, and the attainment of higher concentrations of nicotine all increase the potential for addiction. Nicotine exposure does not have a specific threshold to predict addiction. However, the nicotine source appears to make a difference, with tobacco-delivered nicotine substantially more addictive than pure nicotine. The basis of nicotine addiction is reinforcement of behavior that restores nicotine and makes the user feel pleasure and avoid unpleasant withdrawal. Nicotine addiction among those most heavily affected requires frequent dosing to limit withdrawal symptoms: a 2-pack per

day smoker will have 40 “doses” of nicotine per day, or at approximately 21 minute intervals (if averaged over typical waking hours). Smokers have been shown to report “needing” a cigarette even with intermittent cigarette smoking. Smokers also progress through a characteristic process of nicotine addiction that is characterized by stages: wanting, craving, and needing a cigarette.

The adolescent brain seems uniquely susceptible to nicotine addiction, with symptoms of dependence appearing within days to weeks of intermittent tobacco use and well before daily smoking. Nearly all adult smokers initiated smoking before the age of 20 years, and tobacco use at a younger age predicts greater levels of dependence and difficulty quitting. Animal studies have demonstrated that nicotine exposure during the adolescent period has long-standing effects on the brain, including cell damage that leads to both immediate and persistent behavior changes. These effects are not found with nicotine exposure to the adult. The weight of evidence suggests that nicotine exposure

modifies the developing adolescent brain and has long-term effects into adulthood. Although the evidence showing that cigarette use during adolescence leads to addiction is well established, whether use of noncombustible tobacco products such as e-cigarettes might encourage initiation or transition to combustible tobacco smoking by young people is not yet known. Two early studies assessing combusted tobacco initiation among e-cigarette users found a prospective association between e-cigarette use and subsequent combusted tobacco. A number of studies demonstrate dual use of combusted and noncombusted tobacco products, but provide insufficient data on whether noncombusted tobacco use precedes combusted tobacco use. It has been shown, however, that nicotine replacement therapies have low potential for dependence because of differences in absorption.

Regular users develop habits associated with nicotine use that also become connected with the rewarding feelings of nicotine use, creating cues for use. Known as *operant conditioning*, smokers become cued to want a cigarette after a meal, or with coffee, or in certain locations, for example. These habits of tobacco use are particularly reinforcing, making tobacco use difficult to overcome.

## TOBACCO USE IN ADOLESCENCE AND YOUNG ADULTHOOD

Most young people do not intentionally make the decision to start using tobacco, yet the decision can have significant, lifelong effects. Tobacco use has been aggressively marketed through traditional advertising as well as entertainment media, which has been found to be causally related to adolescent tobacco use. Each day, more than 2,800 US adolescents aged 12 to 17 years try smoking for the first time, with 10.9% of students reporting trying their first cigarette before age 13 years. The likelihood of

subsequent nicotine dependence and addiction is high, and symptoms of addiction appear soon after onset of smoking in some adolescents. While daily smoking in adolescents lags 2 to 3 years behind initiation, roughly 700 adolescents transition to daily smoking each day, and more than 60% of teen smokers still smoke 5 years later. Although most of what is known about youth tobacco use involves cigarettes, a substantial proportion of tobacco use now occurs with tobacco products other than cigarettes, and many youths now use multiple products. Recent data show that nearly 50% of all high school students currently using tobacco use multiple tobacco products concurrently, and some 36% of all current tobacco users do not smoke cigarettes at all. Many youth do not identify themselves as smokers, with occasional, light, or intermediate smoking being common; few youth expect to have difficulty with cessation.

Adolescents underestimate how addictive nicotine is and believe it will be easy to quit; however, relatively few adolescent daily users are successful at quitting. The difficulty that tobacco users face in quitting underscores the importance of prevention. Prevention has become far more complex in recent years with the introduction of new tobacco products to the market such as snus, dissolvables, and e-cigarettes, and the expansion of the flavored “little cigar” and cigarillo market as alternatives to traditional cigarettes. Based on the increase in use of these products as described later in this chapter, these products are expected to be more appealing and may be perceived as less harmful.

### Cigars, Little Filtered Cigars, and Cigarillos

Cigar smoking predates cigarette smoking by hundreds of years and was more popular until the early 1900s (see Figure 338-2). At present, cigars are not regulated by the US Food and Drug Administration

**Figure 338-2** Per capita consumption of different forms of tobacco, 1880–2011. (Adapted from *Patterns of tobacco use among US youth, young adults, and adults*. In: US Department of Health and Human Services. The Health Consequences of Smoking: 50 Years of Progress. A Report of the Surgeon General. Atlanta, GA: US Department of Health and Human Services, Centers for Disease Control and Prevention, National Center for Chronic Disease Prevention and Health Promotion, Office on Smoking and Health; 2014.)

(FDA); however, their use continues to be prevalent among young people and is of significant concern because they currently bypass many of the laws on cigarettes with regard to sales, taxation, and flavors. In contrast to cigarettes, cigars are wrapped in tobacco leaf (rather than paper) and the tobacco differs slightly. While adult users may puff on premium cigars and not inhale them, there is no specific instruction for cigar use; little filtered cigars are in most ways indistinguishable from cigarettes other than color and flavor. At present, cigars are the fourth most common type of tobacco used by youth (behind e-cigarettes, hookah, and cigarettes). In 2014, 8.2% of high school students reported using cigars/cigarillos/little cigars in the past month. An assessment by Monitoring the Future in 2013 found that approximately 20% of high school seniors had used cigars in the past 12 months. Cigars of all types can be sold in characterizing flavors, in packs of small quantity, and are taxed differently, so that they are less expensive than cigarettes. The low price and flavors of these products increase their appeal to youth. Cigar users are at risk for the same health effects as cigarette users.

### Other Combusted Tobacco Products

Waterpipes (hookah) have also recently gained in popularity in the United States, particularly in group social settings and with the advent of “Hookah Bars.” Past-year prevalence of hookah use among 12th graders in 2013 was 21.4%, and past month-use among high school students was 9.4% in 2014. Although many users perceive that smoke inhaled from a hookah is safer than cigarette smoke, studies show that the hookah produces concentrations of carbon monoxide, nicotine, tar, and metals at levels similar to or higher than those produced by cigarettes. Communicable disease risks are significant, given the shared mouthpiece, and herpes outbreaks have been reported from hookah use. In spite of these actual health risks, the misperception of safety and the appeal of social use have attracted non-cigarette users to hookah, and there is the attendant concern that these users will progress to other forms of tobacco and nicotine addiction. Given the popularity of these products, particularly among college students, it is important that physicians ask adolescent patients about them specifically.

### Noncombusted Tobacco Products

Smokeless tobacco, including “dip” and “chew,” has been a common form of tobacco use that was exceeded by combusted tobacco only with the invention of the automated cigarette machine in the early 1900s. The use of smokeless tobacco among youth remains relatively low, but those who use smokeless tobacco use it frequently: it is the tobacco product that has the highest likelihood of daily (or almost-daily) use among high school students. Smokeless products in particular have “starter” class versions that are milder in nicotine content and flavor. Users often progress to a higher nicotine product as their addiction develops. Many users of such products also smoke combusted tobacco products.

The contribution of newer noncombusted products such as electronic nicotine delivery systems (also

known as e-cigarettes or ENDS), snus, and dissolvables to the emergence of tobacco addiction in youth is not yet known, because these products are recent entries to the US market.

### E-cigarettes

E-cigarettes are a category of products that deliver varying amounts of inhaled nicotine and flavoring through a battery-powered device that heats and vaporizes cartridges or tanks filled with solution (see Figure 338-3). Introduced in the United States in 2007, these products are marketed widely on the internet, at point-of-sale outlets, in print and radio media, and on US television as alternatives to cigarette use. Unlike traditional cigarettes, e-cigarettes come in an expansive variety of tobacco, fruit, and food flavors. Given the relatively recent introduction of these devices to the market and rapid evolution of their technology, it is yet to be determined whether they play a role in recruiting new tobacco users or in replacing combusted cigarettes, ceasing tobacco use, or reducing harm. The potential for these devices to introduce non-tobacco users to nicotine addiction or to perpetuate smoking among smokers who would otherwise have quit is of particular concern. Their use among young people is growing: in just 1 year (from 2011 to 2012), the ever and current use of e-cigarettes doubled among US middle- and high school students, and current use then tripled between 2013 and 2014. This

**Figure 338-3** E-cigarette examples and comparators, from top: Refillable tank “pen” system; traditional combusted tobacco cigarette; “cigalike” store-branded disposable e-cigarette; Vuse, a rechargeable cartridge-based e-cigarette; Krave disposable e-cigarette; e-hookah pen; refillable vape pen; e-cigar; another refillable vape pen; and modifiable voltage refillable vaporizer. Note the variations in size and appearance among the 4 refillable tank devices shown.

meteoric rise of e-cigarettes among youth is concerning for various reasons. The e-cigarettes themselves are not without risk, and as previously noted, there is a concern that e-cigarette users will begin using combusted tobacco. While by far most of those who try e-cigarettes have also smoked cigarettes, a proportion of high school ever-users of e-cigarettes have never tried a traditional cigarette. Initiation of e-cigarettes is noted in studies to be directly related to perceptions: young adults who believed that e-cigarettes can help people quit smoking and that e-cigarettes are less harmful than cigarettes were more likely to try e-cigarettes. With tobacco companies now selling e-cigarettes, including Vuse by R.J. Reynolds, MarkTen by NuMark (a subsidiary of Altria), as well as the older Blu e-cig now owned by Lorillard, there is a significant amount of marketing of, and media attention to, e-cigarettes.

E-cigarettes vary dramatically depending on whether they are a disposable or rechargeable cartridge system versus a refillable tank system, and whether the end user can modify the voltage of the device. The nicotine concentration in e-juice solutions ranges vastly from 0 to 100 mg of nicotine in a single milliliter of solution. Producers of this e-juice buy concentrated nicotine and dilute it with propylene glycol or vegetable glycerin to deliver the intended strength, and then add flavor. The creation of this e-juice is at present completely unregulated, and may be done by the end consumer. No standards exist for production, safety, or labeling, and these products have been found to be markedly variable. The availability of tantalizing and delicious-smelling flavors such as “Grape Freeze,” “Simply Mango,” “Death by Chocolate,” “Sour Skittles,” and “Bubblegum Jungle” make these products particularly attractive to youth. Introduction of nicotine to adolescents through the use of e-cigarettes is highly worrisome if these youth become nicotine addicted. As noted, however, the trajectories from e-cigarette initiators are not yet known, and e-cigarette use remains a deeply divisive topic within tobacco control. Many scientists think that e-cigarettes represent a harm-reduction strategy that has substantial promise. Others think that e-cigarettes have intrinsic risks, including the potential to recruit new tobacco users and maintain dual use, and therefore that e-cigarettes represent a net negative to public health. This creates confused messaging arising from public health authorities. The “safest” state is the use of zero tobacco products, including e-cigarettes. Given that vapor, even with low nicotine, contains ultrafine particles with respiratory risks, youth should be warned that “vaping,” even without nicotine, is not a safe experience.

### **Snus and Dissolvables**

Snus and dissolvables have been suggested as safer alternatives to traditional cigarettes and a potential way to decrease the harm caused by combusted tobacco. Adolescents use these forms of tobacco less than cigarettes. Available 2013 data on past-year prevalence among 12th graders is 7.7% for snus and for 1.9% for dissolvable tobacco. Snus is a smokeless tobacco product that does not require the user to spit,

unlike dip or chew. With slogans like “When you can’t smoke, snus,” this tobacco product is marketed specifically as one that can be used in places where smoking is not allowed, and is often cobranded with cigarettes (Marlboro and Camel, for example). The Tobacco Products Scientific Advisory Committee determined that the weight of evidence points to the fact that if an individual were to replace cigarette smoking entirely with snus, the latter would be less harmful than cigarettes. Indeed, those who promote snus as a policy to reduce harm look to Sweden, where snus use is high but smoking prevalence is low. However, some of the product being sold in the United States is qualitatively different from that sold in Sweden, and it appears that more US snus users are engaged in dual use; thus, snus may serve to maintain dependence among smokers who might otherwise have quit.

Dissolvable tobacco products are another new class of smokeless, spitless, finely milled tobacco that dissolves in the mouth until the fine powder is swallowed. Similar to snus, these products have been marketed as tobacco that can be used in places where smoking is prohibited, and are cobranded with traditional cigarettes. Dissolvables are available in mint, wintergreen, cinnamon, and citrus flavors, and are of similar size to candy. While uptake among adolescents has been low to date, ongoing monitoring is warranted, particularly with regard to dual and multiple use.

### **TOXICITY AND POISONING POTENTIAL**

Given the tolerance that occurs with regular nicotine, a wide range of doses have been shown to lead to acute toxicity. Most cases of acute toxicity have been found with accidental ingestion of tobacco or nicotine-containing solutions, or with dermal absorption such as green tobacco sickness. The estimated lethal dose of nicotine is 1 to 13 mg/kg of body weight, with toxicity at lower levels among the nicotine naïve, such as children. Most toxic exposures in youth result in complete recovery; however, there is significant new poisoning potential from nicotine refill solutions for e-cigarettes. E-liquid is a likely candidate for ingestion by young children because it is colorful, candy-flavored, and scented, and often sold without child-proof packaging. Given that nicotine is rapidly dermally absorbed, e-liquid can be dangerous even if it merely comes into contact with the skin. E-liquids are sold in highly concentrated form, with common concentrations containing upwards of 36 mg of nicotine per milliliter of e-liquid. At this concentration, a small 15-mL eye-dropper-sized bottle of e-liquid would contain 540 mg of nicotine. Given the estimated lethal dose range of nicotine, even a single teaspoon of e-liquid at this concentration could kill a small child, and a smaller dose could make a child ill. From the standpoint of risk to young children, it is the flavors and smell that make liquid nicotine refill solutions a prime candidate for accidental ingestion and resultant toxicity. The Centers for Disease Control and Prevention reported that in the month of February 2014 alone, poison control centers received 215 calls related to e-cigarette exposures, many of these in young children. In December 2014, the first child death in the United States from nicotine refill solution was reported.

The Child Nicotine Poisoning Prevention Act of 2015, which would mandate the Consumer Product Safety Commission to require childproof packaging on liquid nicotine, was passed by Congress in January of 2016.

## TOBACCO DEPENDENCE TREATMENT

Although most youth tobacco users want to quit, few seek assistance to do so, and many attempt to quit on their own. Unsurprisingly, most attempts at cessation are unsuccessful, and relapse is frequent. Tobacco cessation is possible, however, as evidenced by the fact that the United States has more former smokers than current smokers. The approach to tobacco cessation is largely the same for adult and adolescent tobacco users, but with a greater emphasis on counseling for adolescents because the evidence for efficacy of pharmacotherapy for this group is insufficient. The Public Health Service (PHS) Clinical Practice Guideline recommends the “5 A’s” model of care (Ask, Advise, Assess, Assist, Arrange follow-up) (see Box 338-1), which has been shown to improve tobacco cessation rates in adults. The first step is to **ASK** about and document all tobacco use at every clinical encounter (including well, ill, and specialty visits). All family members of all ages also should be asked about second-hand smoke exposure, and all families should be advised to make their homes and cars smoke-free. As noted, many youth use both cigarette and noncigarette tobacco products concurrently, so they should be asked about all forms of tobacco use. For all tobacco users, **ADVISE** cessation in a clear, strong manner, personalizing the risks of tobacco use and the benefits of quitting and expressing confidence in the tobacco user’s ability to quit. Regardless of whether the tobacco user is a patient or the parent of a patient, advice should be routinely offered on quitting, helping, and referring all tobacco users. The physician should also **ASSESS** the level of nicotine addiction, reasons for wanting to quit, confidence in ability to quit, and readiness to quit or begin tobacco dependence treatment. In the **ASSIST** step, the physician should initiate treatment, tailoring support to the tobacco user’s readiness to quit and severity of addiction.

Many resources are available to physicians, including self-help materials, referral to statewide or national quitlines (which can provide free telephone counseling to assist tobacco users with cessation), smartphone applications, text support programs, and local community cessation resources. As noted, pharmacotherapy for adolescent tobacco cessation is not recommended by the PHS 2008 guideline because of insufficient evidence of effectiveness. Pharmacotherapy has been demonstrated to be effective in adults, however, and is known to be a safer alternative to tobacco use. Tobacco users should be offered tobacco-cessation medications to assist their quit plan whenever appropriate. These cessation medications include over-the-counter nicotine replacement products (NRT), such as the patch, gum, and lozenge; prescription nicotine inhalers and nasal sprays; bupropion; and varenicline. Details regarding prescription recommendations are available in the PHS Clinical Practice Guideline, but a simple approach would be for a tobacco user to replace each cigarette with a single

### BOX 338-1 The 5 A’s

- Ask
  - Obtain a tobacco use and exposure history from all patients and families
  - Ask about current and past tobacco use and second hand smoke exposure
- Advise
  - Look for “teachable moments”
  - Personalize health risks
    - Use clear, strong, personalized messages: “Smoking is bad for you (and your child). Would you like to quit?” “How can I help you?”
- Assess
  - Determine if the patient is willing to make a behavior change
  - Establish whether he or she is willing to try to quit tobacco use at this time
- Assist
  - Provide information about tobacco use cessation to all tobacco users
  - Strongly urge smoke-free (and tobacco-free) homes
  - Help patients set realistic and specific goals
    - “Quit” date
    - “Smoke-free home” date
  - Help your patient prepare
    - Get support
    - Anticipate challenges
    - Practice problem-solving
    - Provide information about pharmacotherapy and patient resources
    - Provide supplemental materials: Refer to telephone quit lines: 1-800-QUIT NOW
- Arrange Follow Up
  - Plan to follow up on any behavioral commitments
    - Schedule follow-up in person or by telephone soon after important dates, such as quit date or anniversary
- The 6th A – Anticipate
  - Discuss tobacco use with preteens and teens during health supervision visits
    - Include tobacco use with discussions of alcohol, substances of abuse, and sexual activity
- For the Unwilling/Not Ready
  - Discuss the “5 R’s”: Relevance, Risks, Rewards, Roadblocks, and Repetition

lozenge or piece of NRT gum. The strength and frequency of NRT should match the severity of addiction/withdrawal symptoms. As most tobacco users are very familiar with the feeling of using too much tobacco, most tobacco users learn to titrate their NRT dosing just as they learned to titrate their tobacco use. Pediatricians who choose not to prescribe pharmacotherapies should make referrals to cessation services and recommend that parents discuss pharmacotherapies with their health care providers or purchase over-the-counter

products. The final step is to **ARRANGE** follow-up to increase adherence to recommendations.

Motivational interviewing techniques to encourage behavior change should be used throughout all discussions with tobacco users (see Chapter 31, Applying Behavior Change Science; and Chapter 46, Effective Communication Strategies). Encouraging tobacco users to question their own tobacco use and come up with reasons and ways to quit has been shown to be an effective way to motivate change.

## CONCLUSION

Tobacco use remains a preventable and treatable cause of substantial morbidity and mortality in the United States and throughout the world. Pediatricians are well positioned to interact with tobacco users and assist in motivating them to improve their health by quitting tobacco completely. Only with ongoing prevention and treatment strategies will tobacco use be surmounted, and pediatricians and other physicians must be part of this process.

## Chapter 339

# TONSILLECTOMY AND ADENOIDECTOMY

James J. Burns, MD, MPH; D. Gary Griffin, MD, MPH;  
Tara Smith, PharmD; Stephanie Slagle, MD, MPH, MS;  
Evelyn A. Kluka, MD

## INTRODUCTION

Tonsillectomy and adenoidectomy (T/A) are two of the most common surgical procedures performed on children worldwide. Guidelines based on current research define the workup and clinical indications for T/A, and procedural recommendations define best practice. This chapter informs the practicing physician on key issues related to this important and sometimes controversial topic.

## INDICATIONS AND CONTRAINDICATIONS FOR TONSILLECTOMY AND ADENOIDECTOMY

### Obstructive Sleep Apnea Syndrome

Obstructive sleep apnea syndrome (OSAS) is a “disorder of breathing during sleep characterized by prolonged partial upper airway obstruction or intermittent complete obstruction (obstructive apnea) that disrupts normal ventilation during sleep and normal sleep patterns.”
